The classical approach to DNA hybridization involves electrophoretic separation, Southern transfer and membrane hybridization using radioactive probes. Currently, however, the hybridization methods are undergoing a transition from radioactive labels to nonradioactive alternatives, which is driven by the need to enhance the sensitivity and facilitate automation while avoiding the health hazards and inconvenience associated with the use and disposal of radioactive reagents. The labels can be incorporated into the probes either enzymically (e.g. using DNA polymerase or deoxynucleotidyl transferase and modified deoxynucleoside triphosphates) or by chemical conjugation (e.g. introduction of −NH₂ groups into the probe via cytidine transamination and then conjugation to the reporter molecule). Generally, there are two strategies for the analysis of the hybrids. Either the reporter molecule is directly conjugated to the probe, or a ligand is attached to the probe and the hybrids are measured in a subsequent step by adding a specific, labeled binding protein. The ligand may be biotin or a hapten (e.g. digoxigenin). Labeled (strept)avidin or antihapten antibodies may then be employed for detection. Non-radioactive hybridization assays based on fluorescent, chemiluminescent or enzyme labels have been developed. Enzymes (such as alkaline phosphatase and horseradish peroxidase) are the most widely used nonradioactive reporters because they provide amplification through the high turnover of the substrate to the detectable product. The availability of a monoclonal antibody that selectively recognizes double-stranded DNA allowed the development of enzyme immunoassays for hybrids. PCR products are denatured and hybridized to immobilized probe. After washing, the hybrids are determined with an enzyme-labeled anti-double-stranded DNA antibody. Detection is usually based on fluorescence and chemiluminescence. However, the sensitivity of conventional fluorometry is restricted by the high background due to scattering, inherent fluorescence of the sample and luminescence from the cuvettes. Time-resolved fluorometry reduces the background in fluorescence measurements, thus improving the signal-to-noise ratio. This is achieved by using labels with long fluorescence lifetimes, such as the lanthanide ions Eu³⁺, Tb³⁺, Sm³⁺ and Dy³⁺ (Eu³⁺ is the most frequently used label). The sample is excited with a short pulse of light, from a laser or a flash lamp, and the measurement starts only after the short-lived background fluorescence has decayed.

The most successful strategy to attach Eu³⁺ to DNA is to use the isothiocyanate derivative of a complex of Eu³⁺ with an aminopolyacrylic acid. These compounds react easily with primary amino groups that have been introduced in oligonucleotides and deoxynucleoside triphosphates. In one assay format, the PCR products are immobilized on a solid support and detected with a probe labeled with Eu³⁺-chelate. However, the complexes of Eu³⁺ and other lanthanides with aminopolyacrylic acids fluoresce very weakly. For this reason, after the hybridization is completed, an enhancement solution is added which has a low pH (to ensure dissociation of Eu³⁺) and contains a β-diketone (e.g. 2-naphthyltrifluoroacetone) which is an excellent energy donor and forms highly fluorescent complexes with Eu³⁺.

Another approach combines enzymic amplification with the background rejection capabilities of time-resolved fluorometry. This is accomplished by using alkaline phosphatase as a label and the phosphate ester of 5’-fluorosalicylate as a substrate. Enzymic cleavage of the phosphate group produces fluorosalicylate, which forms a long-lived fluorescent ternary complex with Tb³⁺-EDTA at pH12–13. The complex absorbs at a wavelength characteristic of the chelator (337 nm) and emits fluorescence characteristic of Tb³⁺. PCR products are captured in microtiter wells and one strand is removed followed by hybridization to a digoxigenin-labeled probe. The hybrids are determined by using an antidigoxigenin antibody conjugated to alkaline phosphatase and time-resolved fluorometry.

Chemiluminescence is the light emission occurring when chemically excited intermediates or products decay to the electronic ground state. Chemiluminescence provides higher sensitivity than conventional fluorometry because there is no background from excitation light. Acridinium esters were used as chemiluminescent labels in hybridization assays. These molecules react rapidly (1–5 s) with hydrogen peroxide under alkaline conditions to produce light (flash-type reaction). The chemiluminescent decomposition of an acridinium ester involves attack of a peroxide anion at the C-9 ester to form a hydroperoxide, followed by loss of an alcoholate leaving group to produce an unstable dioxetanone. This species decomposes to CO₂ and N-methyl acridone in an electronically excited state. Decay of this molecule
to the ground state is accompanied by light emission at 430 nm. The N-hydroxysuccinimide derivative of acridinium ester reacts with primary amino groups introduced in oligonucleotide probes. Acridinium esters may be used in the analysis of PCR products either in a heterogeneous or a homogeneous assay configuration. Heterogeneous assays involve hybridization in solution and capture of the hybrids on a solid support (e.g. magnetic beads). The homogeneous assay is based on the alkaline hydrolysis of the ester bond of the acridinium molecule, rendering it permanently nonchemiluminescent. Conditions have been developed under which the hydrolysis is slow for the hybridized probe and fast for the free probe. Following hybridization, the reaction conditions are adjusted so that the excess probe is hydrolyzed and the chemiluminescence is a direct measure of the target sequence.\(^{(26)}\)

The photoprotein aequorin has also been used as a reporter in chemiluminescence hybridization assays of amplified sequences. Aequorin is a complex of apoaequorin (a single polypeptide chain of 189 amino acids), the cofactor coelenterazine and molecular oxygen. Upon Ca\(^{2+}\) binding to aequorin, a flash-type luminescent reaction is triggered which yields apoaequorin coelenteramide, CO\(_2\) and light at 469 nm with a quantum yield of 15\%. Microtiter well-based sandwich-type hybridization assays have been developed in which the PCR product is denatured and hybridized simultaneously with an immobilized capture probe and a biotinylated detection probe. The hybrids are measured by using streptavidin–aequorin conjugates.\(^{(27)}\)

Enzyme labels, such as alkaline phosphatase and horseradish peroxidase, can be combined with chemiluminesgenic substrates for determination of amplified DNA. The adamantyl 1,2-dioxetane aryl phosphates, such as disodium 3-[4-methoxyisopropyl]-1,2-dioxetane-3,2′-(5′-chloro)tricyclo[3,3,1.1.3.7]-decan-4-yl-phenylphosphate (CSPD), are the most widely used substrates. Enzymic dephosphorylation of this molecule gives a phenoxide intermediate and this decomposes to produce light emission at 470 nm (glow type reaction).\(^{(26)}\)

Electrochemiluminescence is the chemiluminescent reaction of species that are generated electrochemically at the surface of an electrode. The complex tris(2,2′-bipyridine)ruthenium (II) chelate \([\text{Ru(bpy)}_3]^{2+}\) has been used as an electrochemiluminescent label in the analysis of PCR products.\(^{(29,30)}\) When the voltage in an electrochemical cell becomes greater than a threshold value, \([\text{Ru(bpy)}_3]^{2+}\) is oxidized at the surface of the anode to give \([\text{Ru(bpy)}_3]^{3+}\). Tripropylamine (TPA), which is present in large excess in the assay buffer, is also oxidized simultaneously at the electrode to TPA\(^{**}\), which after deprotonation gives the strong reductant TPA\(^*\). \([\text{Ru(bpy)}_3]^{3+}\) undergoes reduction from TPA\(^*\) with production of the excited electronic state of \([\text{Ru(bpy)}_3]^{2+}\), which upon returning to the ground state emits a photon at 620 nm. An important feature of electrochemiluminescence is that the light-emitting reaction regenerates the original \([\text{Ru(bpy)}_3]^{2+}\) species which is then available to enter another cycle of oxidation and light emission. Thus, many photons are emitted from each \([\text{Ru(bpy)}_3]^{2+}\) label.

In a typical assay protocol, one of the PCR primers is biotinylated at the 5′ end. \([\text{Ru(bpy)}_3]^{2+}\) is attached to an oligonucleotide probe complementary to the biotinylated strand. Following PCR, the products are denatured, hybridized with the probe and captured to magnetic beads coated with streptavidin. A suspension of the beads is then introduced in the flow cell of the instrument (QPCR system 5000). A magnetic arm immobilizes the beads on the surface of the working electrode and allows washing with a TPA-containing buffer. Then voltage is applied and the luminescence is measured with a photomultiplier mounted closely to the flow cell. In an alternative protocol, \([\text{Ru(bpy)}_3]^{2+}\) is attached to the primer and incorporated into the amplified sequences, thus leading to double-labeled (biotin and \([\text{Ru(bpy)}_3]^{2+}\)) DNA fragments that are captured to the beads and measured directly.

In recent years methods have been developed for continuous determination of the products generated during PCR, i.e. for real-time monitoring of DNA amplification.\(^{(31–33)}\) One such approach uses the compound SYBR Green I, whose fluorescence increases upon binding to double-stranded DNA. A limitation of this method is that nonspecific products are co-determined. An alternative strategy employs an oligonucleotide probe that is labeled with a donor fluorescent molecule (6-carboxyfluorescein) at the 5′ end and an acceptor molecule (6-carboxytetramethylrhodamine) downstream a short distance. The probe is modified at the 3′ end to block its extension by the polymerase. The close proximity between donor and acceptor allows for energy transfer to occur and, therefore, no fluorescence from the donor is observed. During annealing, the probe hybridizes to the template DNA at a position flanked by the primers. However, because of the 5′ exonuclease activity of Taq DNA polymerase,\(^{(34)}\) the hybridized probe is hydrolyzed during the extension phase of each cycle and the fluorescence increases.

A fluorometer with microvolume multisample capabilities and temperature control for real-time monitoring of PCR has been described.\(^{(35)}\) Complete amplification and analysis requires 10–15 min (for 30 cycles). The samples are introduced in glass capillaries that facilitate heat transfer and also serve as cuvettes. The heating is by forced air.

Molecular beacons (oligonucleotide probes that consist of a stem-and-loop structure) have been used for monitoring of PCR product formation in a homogeneous
format during or after amplification. The loop part of the beacon is a single-stranded probe complementary to the target sequence. The stem is formed by extending each side of the probe with two oligonucleotide arms that are complementary to each other but unrelated to the target (the stem is a double helix). A donor fluorescent molecule is attached to the end of one arm and an acceptor molecule is attached to the other end. The close proximity between donor and acceptor in the stem structure allows for energy transfer to occur and, therefore, no fluorescence from the donor is observed. Upon hybridization of the probe region (loop) with the target sequence the double-stranded stem structure undergoes a conformational reorganization (strand separation) that places the donor and acceptor molecules far enough apart and the molecular beacon fluoresces. The dissociation of the stem strands is due to the fact that the probe–target hybrid is longer and more stable than the stem hybrid. It has been shown that the hairpin stem structure enhances the specificity of molecular beacons, enabling them to distinguish targets differing by a single nucleotide. Furthermore, several molecular beacons attached to different fluorophores can be used to monitor the accumulation of multiple targets in the same PCR.\(^{36,37}\)

Oligonucleotide probes labeled with the fluorescent phthalocyanine dye La Jolla Blue were used for a homogeneous assay of PCR products by transient-state polarized fluorescence.\(^{38}\) The dye has absorbance and emission maxima at 685 nm and 705 nm, respectively. Hybridization of the La Jolla Blue–oligonucleotide conjugate with the target results in longer rotational relaxation time of the hybrid and an increase in polarized fluorescence.

5 QUANTITATIVE POLYMERASE CHAIN REACTION

Perhaps the most challenging analytical problem associated with PCR is the determination of the amount of starting material, i.e. relating the analytical signal obtained from the amplification product to the initial number of target DNA or RNA molecules present in the sample prior to amplification.

The accumulation of product during the exponential phase of PCR can be described by Equation (1):

$$P = T(1 + E)^n$$  \(1\)

where \(P\) is the amount of amplification product, \(T\) is the initial amount of target DNA, \(n\) is the number of amplification cycles and \(E\) is the average efficiency of the reaction for each cycle. The theoretical value of \(E\) is 1 but usually it has a lower value. The above equation shows that, in the exponential phase, there is a linear relationship between the amount of product and the amount of input DNA. If \(E\) was constant, then determination of \(T\) could be accomplished simply by constructing a calibration curve with known amounts of a DNA standard (under constant \(n\)). The slope of the line would be equal to \((1 + E)^n\). However, the value of \(E\) depends on the sample and the reaction conditions. Moreover, small sample-to-sample variations in \(E\) lead to dramatic changes in the amount of product and large errors in estimating the initial quantity of target (especially when the cycle number is large). For instance, a 5% decrease in \(E\) (e.g. from 1 to 0.95) leads to an almost 50% decrease in the amount of product (when \(n = 25\)). In situations where quantitative analysis of RNA is being performed, the variation in the efficiency of reverse transcription should be taken into account.

One approach to quantitative PCR is to use an endogenous but unrelated sequence as an internal standard.\(^{40,41}\) The standard is amplified with a different pair of primers either in a separate or in the same reaction tube. Thus, the ratio of the amplification products from target and internal standard is expected to be a linear function of the ratio of target DNA/internal standard molecules prior to amplification. This approach requires that the PCR for both the target DNA and the internal standard must be restricted to the exponential phase of product accumulation. If there is a large difference in the concentrations of target and internal standard, then the plateau phase will be reached much more rapidly for the one present at higher concentration and the ratio of the products will not reflect the ratio of the initial concentrations. This problem can be resolved by an appropriate dilution before PCR.

A DNA sequence from a single copy gene can be used as an internal standard for gene dosage studies. In the case of RNA determination, a cellular RNA whose expression level is constant between samples is employed. This process also corrects for inter-sample variation in RNA isolation and for any loss of template due to ribonucleases. The most widely used endogenous standards are RNAs from housekeeping genes such as \(\beta\)-actin and glyceraldehyde-3-phosphate dehydrogenase. Therefore, this approach provides the relative expression of the gene of interest with respect to a housekeeping gene but it does not give the absolute number of mRNA copies. A crucial assumption is that the housekeeping gene has an even rate of transcription among different tissues of an organism, at all stages of development and in all experimental treatments. However, it has been reported that \(\beta\)-actin mRNA concentrations increase with the malignant transformation of cells.\(^{42}\)

Another approach to compensate for the variability in the efficiency is based on the co-amplification of the target
DNA or RNA with a known amount of recombinant DNA or RNA internal standard, respectively. The internal standard is engineered to contain the same primer binding sites and to resemble as closely as possible the target sequence. Thus, any changes in the amplification efficiency are expected to affect both amplifications equally so that the ratio of the reaction products reflects the ratio of the two nucleic acid sequences in the starting mixture. Furthermore, the PCR products of target and internal standard should be distinguishable by size, hybridization or change in a restriction site. In the case of RNA analysis, RNA internal standards are advantageous compared to DNA standards because they allow compensation for any variation in the efficiency of both the reverse transcription and subsequent amplification. In the majority of reports the internal standard is designed to contain a deletion or insertion large enough to allow electrophoretic separation of the amplification products. Each DNA fragment is then quantified by ethidium bromide staining followed by scanning densitometry. In one widely used protocol, an increasing amount of internal standard is added separately to the same amount of target sequence followed by amplification. The goal is to find the amount of standard at which target and standard give an identical signal upon staining after agarose gel electrophoresis. Equal amounts of the two PCR products imply identical quantities prior to amplification. Thus, the ratios of the amplification products for target and standard are plotted as a function of the amount of internal standard and the point at which the ratio has a value of 1 is found by interpolation. The method provides absolute quantification of the target sequence. One of the main benefits of using a recombinant internal standard with the same primer binding sites as the target sequence is that it is not necessary to restrict the data acquisition in the exponential phase of amplification because the initial target to standard ratio remains the same even if the reaction proceeds to the plateau phase.

It has been shown that the amplification efficiency is inversely related to the size of the DNA. Thus, the internal standard should have a similar size to the target sequence. For this reason, internal standards that differ from the target only in a restriction site have been constructed. Following amplification, the products are digested and separated electrophoretically. It has been observed however that co-amplification of DNA fragments that share considerable sequence homology leads to the formation of heteroduplexes during PCR even if their sizes are different. During the annealing phase of a PCR cycle, a fraction of the single-stranded fragments of target DNA will hybridize with the complementary strand from the internal standard and vice versa. Heteroduplex formation poses serious problems with the analysis of the products by electrophoresis and HPLC. Upon electrophoresis the heteroduplexes may migrate between the target DNA and the internal standard, causing errors in the determination of the products, especially if they cannot be resolved from the homoduplexes. In the case of an internal standard having the same size as the target but differing only in a restriction site, the heteroduplexes interfere because they are resistant to digestion.

An internal standard that is distinguishable by hybridization has identical size to the target but contains a characteristic sequence to allow hybridization with a specific probe. Analysis of the products includes a denaturation step prior to hybridization. Consequently, heteroduplex formation is not a concern for this method. Microtiter-well-based hybridization with nonradioactive detection is preferred because it facilitates automation and high-throughput analysis. One hybridization configuration involves capture of biotinylated products on streptavidin coated wells, removal of one strand with NaOH treatment and hybridization with probes specific for the target and the internal standard. Alternatively, the PCR products are denatured and allowed to hybridize with an immobilized capture probe and a labeled detection probe. Both configurations require splitting of each sample in different reaction vessels (wells). Recently, a dual-analyte chemiluminescence hybridization assay was developed for simultaneous determination of the amplified target and internal standard in the same well. The amplified target was hybridized with a digoxigenin-labeled probe and detected by using antidigoxigenin antibody labeled with aequorin. The amplified internal standard was hybridized, in the same well, with a fluorescein-labeled probe and the hybrids were determined by using antifluorescein antibody conjugated to alkaline phosphatase. Aequorin was quantified by adding a Ca$^{2+}$-containing triggering solution and alkaline phosphatase was measured by using a dioxetane chemiluminogenic substrate. Fluorometric methods that allow for homogeneous real-time monitoring of PCR products (as described in section 4) are also used in quantitative PCR or RT-PCR. Specific probes labeled with different donor molecules and the same acceptor molecule may be used for determination of amplified target DNA and internal standard. In this approach, quantification is accomplished by measuring the number of cycles required to reach a certain fluorescent signal that corresponds to a concentration of PCR product that is clearly within the exponential phase of amplification. Indeed, by taking the logarithm of Equation (1) and solving for $n$, we have Equation (2):
Equation (2) shows that if PCRs (performed with various amounts of input DNA) are stopped when a predetermined level of amplification product is generated, then the cycle number is linearly related to the logarithm of target DNA molecules. For Equation (2) to be valid, the PCR must be in the exponential phase of product accumulation.

Real-time quantitative PCR methods are advantageous in that they do not require post-PCR sample processing and they are easily automatable. However, the detectability of the fluorescent label is in the nanomole per liter range and the fluorescence value provides an indirect measure of the amplification product. On the other hand, post-PCR chemiluminescence and time-resolved fluorescence hybridization assays offer 1000 times higher sensitivity since they can detect amplification products in pmoles per liter.

6 IMMUNO-POLYMERASE CHAIN REACTION

Immuno-PCR is an immunoassay in which a DNA fragment is used as a label. After completion of the immunoreaction, the label is subjected to PCR amplification and the products are detected by gel electrophoresis or enzyme-linked immunosorbent assay.

7 LIGASE CHAIN REACTION

LCR is an exponential in vitro amplification technique that employs a thermostable ligase and allows the discrimination of DNA sequences differing in only a single base pair. The principle of LCR is as follows (Figure 2): First, the DNA target is denatured at 95°C. Then, two allele-specific oligonucleotide probes are allowed to hybridize at adjacent positions (no gap) of the sense strand of target DNA at 60–65°C. In a similar manner, a second pair of probes hybridizes with the antisense strand of the target sequence. The junction of the primers is positioned so that the nucleotide at the 3’ end of the upstream primer coincides with a potential base difference in the target sequence. The probes are joined by ligase and the products can serve as templates in the next reaction cycle, leading to an exponential amplification process. If there is a mismatch at the primer junction, the primers will not be ligated and amplification product will not be formed. A second set of four oligonucleotides can be used in a separate reaction to detect the mutant allele.

PLCR (a modification of LCR) is used for allele-specific DNA amplification and detection using the Stoffel fragment of Taq DNA polymerase and a thermostable ligase. After DNA denaturation, two pairs of complementary but not adjacent oligonucleotides are allowed to anneal with the sense and antisense strand of the target sequence, respectively. These primers anneal so that there is a 2–3 nucleotide gap between each other. The Stoffel fragment, lacking not only the 3’ → 5’ proofreading exonuclease activity but also the 5’ → 3’ exonuclease activity, can fill the gap with the appropriate dNTPs and subsequently the ligase will link the nick.

The classical approach to detection of LCR products involves labeling the upstream primer with 32P at the 3’ end, separation of the LCR products by denaturing gel electrophoresis and autoradiography. Another approach employs fluorescently labeled probes that allow for analysis of LCR products by using a fluorometric DNA sequencer. Microtiter-well-based methods for determination of LCR products use one probe labeled at the 5’ end with biotin and the other probe conjugated to a non-radioactive reporter molecule (e.g. 5’-carboxyfluorescein or digoxigenin). LCR is often utilized in conjunction with an initial PCR amplification to achieve higher sensitivity.

8 SELF-SUSTAINED SEQUENCE REPLICATION AND NUCLEIC ACID SEQUENCE-BASED AMPLIFICATION

3SR and NASBA are isothermal techniques for in vitro amplification of target RNA or DNA by the simultaneous concerted action of AMV reverse transcriptase, ribonuclease H (RNase H) and T7 RNA
Figure 3 Schematic illustration of the principle of 3SR and NASBA systems. P₁, primer containing the T7 promoter sequence (T7) at the 5′ end; RT, reverse transcriptase; RNase H, ribonuclease H; P₂, second primer.

POLYMERASE CHAIN REACTION AND OTHER AMPLIFICATION SYSTEMS

Polymerase. The major amplification product is single-stranded RNA but RNA:DNA hybrids and double-stranded DNA are also synthesized, although to a minor extent. The amplification steps are shown in Figure 3. The reaction begins by annealing of the first primer on the RNA target. The primer carries a T7 promoter sequence at the 5′ end. Reverse transcriptase then synthesizes a complementary DNA strand resulting in a DNA:RNA hybrid. RNase H then hydrolyzes the RNA strand of DNA:RNA hybrids thus leaving single-stranded DNA. Subsequently a second primer anneals to the DNA strand followed by the synthesis of a complementary strand of DNA by reverse transcriptase. This double-stranded DNA carries the T7 promoter sequence and serves as a template for T7 RNA polymerase that synthesizes many copies of RNA transcripts. Each of the newly synthesized RNA molecules re-enters the cycle and serves as a template for a new round of amplification leading to an exponential accumulation of the product. An amplification of $10^9$ fold is achieved in about 2 h.

It has been shown that with an initial denaturation step this system could be modified to amplify DNA but the product of the reaction is always RNA. It was found that the presence of dimethylsulfoxide (DMSO) and sorbitol in the reaction mixture enhances the RNase activity of AMV reverse transcriptase sufficiently to allow the reaction to proceed without RNase H. Alternatively, human immunodeficiency virus (HIV) reverse transcriptase may be used instead of AMV reverse transcriptase to allow RNase H to be omitted.

Amplification products are determined by methods similar to those used in the analysis of PCR products.

9 STRAND DISPLACEMENT AMPLIFICATION

SDA is an isothermal in vitro method for amplifying DNA sequences. The technique is based on the ability of a restriction enzyme to nick the unmodified strand of a hemimodified restriction site and the ability of a 5′→3′ exonuclease-deficient DNA polymerase to extend the 3′ end at the nick and displace the downstream strand. The target DNA is heat-denatured in the presence of all reagents except the restriction enzyme and the polymerase. Two primers bind to opposite strands of the DNA. At their 5′ ends the primers contain a recognition site for a restriction endonuclease (e.g. Hinc II). DNA replication using dCTP, dGTP, dTTP and dATP produces a double-stranded hemiphosphorothioate recognition site. Hinc II nicks the unprotected primer strand leaving intact the modified complementary strand. DNA polymerase then extends the 3′ end at the nick and displaces the downstream fragment. The polymerization/displacement step regenerates a nickable recognition site. Target amplification by SDA is exponential because each displaced strand serves as target for the other primer (i.e. the primer that was extended for synthesis of the complementary strand).

Methods for analysis of SDA products include hybridization with 32P-labeled probes or nonradioactive hybridization assay configurations. More recently, fluorescence polarization was employed for real-time monitoring of SDA products.

Radiation hybrid (RH) mapping is a convenient and widely used method for rapidly locating new DNA sequences on genomes in relation to other DNA markers. The aim of the technique is to determine the correct order and relative distances between a set of markers, or to locate a new marker to its most likely location on a genome. We review the history of the technique, its current status, and the main analytical techniques used to generate maps from raw data.

The physical processes and assumptions underlying the technique are examined. These processes are used to derive models from which the required information, location of markers with respect to each other on a linear map of DNA, is obtained by a variety of computational means.

The RH technique has proved indispensable in mapping the human genome, since, unlike genetic mapping, the conditions under which panels are made is completely under experimental control, so mapping at any degree of resolution is possible. The other major advantage of RH mapping over genetic mapping is that markers need not be polymorphic; it is presence or absence of a marker that is detected, not type. It has therefore been used to map the large numbers of expressed sequence tags that have been generated as part of the human genome project (HGP). This has given rise to the first human gene map and subsequent updates, so that currently 40,000 genes have been assigned locations on the human genome.
1 INTRODUCTION

A genetic linkage map comprises the locations and relative distances between genes and other unique DNA sequences on linear maps corresponding to different chromosomes. Genetic linkage maps are a fundamental tool in modern biological research. They enable identification, cloning and sequencing of new genes by localizing the area of the genome in which the gene is located. They also allow identification of conserved regions between genomes of different species, which can be used to identify previously undetected genes. They have been used extensively in the study of human genetic disease and economically important agricultural species (plants and livestock). High-resolution maps of the entire human genome have been constructed and are being used as the framework on which to place the complete DNA sequence at their correct positions on the genome as part of the HGP. It is expected that 95% of the human DNA sequence will have been measured by the middle of the year 2000.

The first genetic maps were constructed in the early part of this century by observing the inheritance of different traits in successive generations of natural populations or artificial crosses. More recently, this technique of “genetic mapping” has been superseded by the technique of “RH mapping”, which enables many more markers to be mapped faster and using fewer resources. Many of the assumptions on which RH mapping is based derive from conclusions from genetic mapping. The most important of these are that genes are located relative to each other on linear maps, and the distances between different pairs of genes can be determined from experimental observations. The key experiments that led to these conclusions are now reviewed.

1.1 Experimental Evidence for Linear Genetic Maps

Mendel first demonstrated that individual traits of appearance could be inherited. He treated these traits (genes) as being independent of each other, and predicted the frequencies of different combinations of traits that should be observed given their independent inheritance. It was soon discovered that, rather than being independent, the genes occurred in a relatively small number of tightly linked groups. This was deduced by Bateson and Punnett, who observed significant deviations from the distributions expected from independent inheritance. Certain pairs of genes were inherited from either one parent or the other more frequently than expected. Morgan interpreted these “linkage groups” as corresponding to the physical chromosomes: genes on the same chromosome would be inherited more often together than independently. Drosophila was observed to have 4 linkage groups, maize 10, yeast 17, mouse 20, and human 23.

Within each linkage group, the strength of linkage between pairs of genes was observed to vary. It was quantified by observing how frequently a pair of genes were inherited from just one parent. The phenomenon of “crossing-over” of genetic material had been discovered to be the mechanism for sharing genes from both parents to the offspring, and was identified with the physical structures known as chiasmata. These occur during meiosis between the paired chromosomes of the parents, and function to exchange, or “recombine”, genetic material between homologous chromosomes from the two parents, thereby achieving some mixing of genes on the corresponding chromosome in the offspring. The further apart are two genes, the more likely it is they have been exchanged by a crossover, and the weaker the observed linkage. The degree of linkage between a pair of genes was quantified by the “recombination frequency”, $\theta$, the fraction of offspring that contain one gene from one of the parents, and the second gene from the other parent. A genetic map unit (m.u.) was defined as that distance between genes for which the 1 product of meiosis out of 100 is recombinant, $\theta_{AB} = 0.01$. The map unit is also called a centimorgan (cM) which corresponds to a physical molecular distance of approximately 1 Mb (megabase or $10^6$ base pairs) in humans. That is, 1 crossover occurs on average every 100 Mb in the human genome (see Analytical methods). Therefore, a measure of the association between two genes could be used as a measure of the physical distance separating them on a linear chromosome. It enabled estimates of physical distances between genes from observed measures of association.

1.2 Use of the Recombination Frequency to Construct Linear Maps

Sturtevant, a student of Morgan, examined whether linear maps could be constructed using the recombination frequency directly as a measure of distance between genes on the same chromosome. He found that for small values of $\theta$, genes could be ordered on a linear map. For example, if three genes A, B, and C had recombination frequencies $\theta_{AB} = 0.01$, $\theta_{BC} = 0.03$, and $\theta_{AC} = 0.04$, the correct order and distances between adjacent markers is A–(0.01)–B–(0.03)–C. However, for larger values of $\theta$, it was observed that it underestimated distances, and genes could no longer be arranged linearly. For example, if $\theta_{AB} = \theta_{BC} = 0.2$, then $\theta_{AC}$ would typically be ~0.3, and the markers could no longer be accurately represented on a linear map. $\theta$ reaches a maximum value of 0.5 when the genes are completely unlinked on separate chromosomes.

The nonlinearity of the recombination frequency for larger values was explained by the occurrence of more than one crossover in larger intervals. A double
crossover would be counted as a nonrecombinant, and the recombination frequency would therefore underestimate true physical distance. The relationship between recombination frequency and physical distance is examined further in Analytical methods. These discoveries made in genetic mapping with respect to the relationship between the observed association and physical distance were of fundamental importance for the interpretation of results from RH mapping.

Although many genes have been mapped using classical genetic mapping, a fundamental limitation of the technique is the requirement that the gene should be polymorphic, i.e. show measurably different forms such as in eye color or flower shape. Many genes in the genome are thought not to show detectably variant forms, and therefore cannot be located on the genome using genetic mapping.

1.3 Somatic Cell (Goss–Harris) Mapping

An entirely different method for determining linkage between genes and the corresponding distances between them was demonstrated in 1975 by Goss and Harris. Rather than relying on observations of naturally occurring crossovers to quantify linkage between genes, they physically disrupted human chromosomes by irradiating whole cells with X-rays. Linkage could then be detected by how much the genes were randomized in the process. The result of irradiation was a series of chromosomal fragments, whose size was dependent on the X-ray dose; larger doses caused more fragmentation and smaller fragments. These fragments were then fused with unirradiated hamster cells to form so-called “somatic cell hybrids”, i.e. nongermline cells which contained DNA from two different species. A number of individual hybrid cells were cultivated, each hybrid containing an independent and random sample of the fragments. In the original experiment, the initial cells of each hybrid colony were selected if they retained human fragments expressing the enzyme HGRT (hypoxanthine guanine phosphoribosyl transterase), by growing on HAT (hypoxanthine, aminopterin, thymidine) medium. This complemented the lack of HGRT, which is located on the long arm of the human X chromosome. Hamster cells that did not retain chromosomal fragments containing HGRT did not survive the selective medium. The frequency with which three other human genes on the X chromosome were co-transferred with the selected marker was measured, and interpreted in terms of how strongly “linked” they were. The data showed that one of the genes (PGK) segregates from the selected gene (HGRT) more frequently than do the other two genes (α-gal and G6PD). This was interpreted as due to PGK being further apart from HGRT than are the other two genes, since the closer that two markers are together, the less likely it is that they will be separated by X-rays. A quantitative treatment was developed which allowed distance, in units of the mean number of breaks that occur between pairs of markers, to be estimated directly from the observed frequency of coretention in the hybrid panel. From these observations, Goss and Harris were able to determine the order and relative distances between the four genes.

In a second experiment, Goss and Harris constructed a human–mouse panel, which retained fragments even if they did not contain a selected gene such as HGRT. The analysis became more involved, since a hybrid typed positive for two genes could be due to their dependent retention on the same fragment or independent retention of both genes on different fragments. Methods were developed by which the observed distribution of the number of different hybrid types could be used to estimate distances between pairs of markers. Mapping of any region of the genome could be accomplished with this panel, since the restriction of having a selectable marker had been removed. Their quantitative treatment of the observations is described in Analytical methods.

1.4 Radiation Hybrid Mapping

The method was underused until its revival in 1989/90 by Cox et al. This was attributed to a lack of sufficient markers to exploit the technology. Cox et al. constructed a human–hamster hybrid panel which also contained human fragments without the need for specific selection. Their approach differed slightly from Goss and Harris’s nonselective method by using a rodent–human somatic cell hybrid that contained a single chromosome as the donor cell, rather than a diploid human cell. The advantage of this technique was that all fragments retained in the RH were known to originate from a single known human chromosome. They demonstrated the technique by localizing a 10–20 Mb region on chromosome 4 in the region of the Huntington Disease gene. It was subsequently used to map 20 genes on the proximal half of chromosome 21 and 21 genes on the distal half. The authors also generated expressions relating retention frequencies to physical distances, along similar lines to Goss and Harris. These are described in Analytical methods. Some differences between genetic mapping and RH (Goss–Harris) mapping are shown in Table 1.

1.5 Whole-genome Radiation Hybrid Mapping

Walter et al. returned to the original methods of Goss and Harris, by using as a donor cell a diploid human cell (fibroblast) rather than a human–rodent hybrid cell.

containing a single human chromosome. This enabled mapping of all regions of the human genome, not just a single chromosome, using a single RH panel.

1.6 Growth of the Field

Following the publication of the 1990 Cox paper,\(^6\) there was enormous renewed interest in the technique, stimulating many new studies and the development of many new analytical techniques. This was partly due to the large number of novel markers that had been generated in the early 1990s for the construction of high-resolution genetic maps of the human\(^9\) and mouse\(^10\) genomes. These unique DNA sequences were readily available for independent mapping using the complementary technique of RH mapping. Since the underlying order and physical distances between markers on chromosomes is thought to be largely constant, comparison of the maps generated by genetic mapping and RH mapping would reveal important differences between the techniques. An example would be the identification of regions of the genome that have a higher occurrence of crossovers (recombination “hot-spots”) which would inflate distances on the genetic map with respect to the corresponding region on the RH map. Such “hot-spots” have often been implicated in disease. These studies continue as data accumulates.

The considerable theoretical background developed for genetic mapping was also used with some modifications in the development of new techniques for analyzing results from RH experiments. Therefore, although the physical processes underlying RH mapping are fundamentally different from those in genetic mapping, the analytical techniques used rely heavily on previous results from genetic mapping work.

2 CONSTRUCTION OF A RADIATION HYBRID PANEL IN SILICO

The processes occurring during construction of an RH panel can be visualized using Monte Carlo simulation techniques. We follow the steps of the experiment in silico as they are thought to occur in vitro.

1. We assume a 1–1 relationship between an irradiated cell and the recipient hybrid cell that will “retain” the fragments of the donor chromosomes. For a panel comprising 50 hybrids, we assume that each of the 50 recipient cells “retains” the fragments resulting from irradiation of 1 of 50 donor cells. The 50 donor chromosomes are represented as vertical lines in Figure 1(a).

2. Each of the donor chromosomes is independently irradiated, causing the donor chromosome to break at random and independent locations. The number of breaks occurring on a chromosome is proportional to the X-ray dose and the length of the chromosome. We chose a chromosome of arbitrary length 5, meaning that on average there are five breaks per chromosome. The actual number of breaks is chosen from a Poisson distribution with mean and standard deviation equal to 5, and this number of breaks is placed uniformly randomly on the chromosome. The positions of the breaks on each chromosome are represented as small horizontal lines.

3. Each recipient cell “retains” a certain fraction of the fragments of its donor chromosome by randomly selecting them from the fragment pool generated by breakage. This fraction is chosen to correspond to experimentally observed marker retention frequencies. Here we choose the retention frequency to 0.5, which maximizes the information provided by each marker. Retained fragments are drawn in black in Figure 1(a); fragments not retained are drawn in gray.

4. The positions of 50 randomly placed markers are shown at the right-hand edge of Figure 1(a).

5. Each of these markers is “typed” on each of the recipient hybrid cells for presence or absence, and the result is shown in Figure 1(b), in which each row corresponds to one marker, and each column is one recipient hybrid cell. Black indicates presence of a marker in a hybrid cell, and white absence.

6. In general, marker order is not known, so the order of markers in Figure 1(b) is randomized in Figure 1(c) (the rows are scrambled). Figure 1(c) is a typical starting point for construction of a chromosome map using RHs, with the rows in arbitrary order, i.e. the markers are in no particular order.

The goal of an RH panel, starting from Figure 1(c), is to determine the correct order of markers (Figure 1c → Figure 1b). Then the correct distances between adjacent markers should be obtained (Figure 1b → Figure 1a).
RADIATION HYBRID MAPPING

Figure 1 Simulation of an RH experiment. (a) Individual chromosomes are fragmented with X-rays, average of five breaks per chromosome, defining its length as 5R (5 Rays where 1 Ray is the distance interval in which 1 break occurs on average; 5 Rays is the distance in which 5 breaks occur on average). Positions of breaks are indicated on each column (chromosome) by small horizontal lines. Fragments are retained (black lines) or lost to the medium (gray lines). (b) Fifty markers are placed randomly on the chromosomes (at the same positions on each chromosome). These positions are indicated by short horizontal lines at the right-hand edge of (a). The lines joining (a) to (b) remove the interlocus distance information. The actual positions of the markers are on the left, their order on the right. The histogram to the right of (b) shows the number of chromosome breaks that have occurred between adjacent loci. Large numbers of breaks are clearly reflected as horizontal discontinuities in the marker retention pattern. (c) The order of the markers is randomized, and it is usually in this form that raw data exist before any mapping. There are 89 obligate breaks in the ordered set, and 759 in the randomized set.

3 ANALYTICAL METHODS

The process of constructing a map from experimental data involves two steps: detection and quantification of linkage in terms of physical distance between pairs of markers, and subsequently placing the markers on a linear map which best explains the physical distances. Many different methods have been developed, typically first for meiotic linkage mapping, since it has been in practice for much longer than RH mapping, then subsequently applied with modifications to RH data.

The experimental data from both meiotic mapping and RH mapping is used initially to determine whether there is any association between pairs of markers. Association can be quantified in two respects: the strength of the association; and its significance. The strength of association is greater for markers closer to each other, and can therefore be used as a measure of physical distance. It is measured as $q$, the recombination frequency in genetic mapping or the breakage frequency in RH mapping, between a pair of markers. The signficance of the association measures how likely the observed association would be to arise by chance, and is used to attach some “confidence” to the associated strength, and is usually expressed as a log-of-odds (lod) score, denoted $Z(\theta)$, which is the log of the likelihood of obtaining the observed value of $\theta$ if the markers were not linked. The significance of an observation increases with the number of samples taken (e.g. number of offspring in a genetic cross or number of hybrids in a RH panel), and allows weaker associations to be measured with more confidence that they are not due only to random fluctuations.

3.1 Strength of Linkage in Meiotic Maps

Results from genetic crosses indicated that certain pairs of genes appeared to be inherited together more frequently than would be expected if their inheritance were independent. The degree of linkage (or its complement, random inheritance) was quantified by counting the number of offspring that inherited genes from different parents (recombinants). These arise from the occurrence of “crossovers” during meiosis, which exchange genetic material between the parental chromosomes. Analysis of the structure of crossovers, which indicated a strictly reciprocal exchange of genetic material, shows that if two markers are separated by 1 or more crossovers, the frequency of recombinants in the offspring will be 0.5. If two markers are not separated by a crossover, the frequency of recombinants (recombination frequency) is 0.0. Intermediate values of the recombination frequency
are then determined by the probability that 1 or more crossovers have occurred between markers. The reciprocal exchange of genetic material from the two parents at each crossover enables $$\theta$$ to be estimated directly from the number of recombinant offspring.

Haldane(11) assumed that crossovers occurred randomly and independently of each other. The number of crossovers in a given interval is then given by the Poisson distribution. If the rate of occurrence of crossovers in a unit interval of distance is $$\lambda$$, then the probability of observing $$n$$ crossovers in a given interval with length $$D$$ is given by Equation (1)

$$p_n = \frac{1}{n!} \lambda^n e^{-\lambda D}$$

(1)

In particular, the probability that no crossovers have occurred between two markers separated by a distance $$D$$ is given by Equation (2)

$$p_0 = e^{-\lambda D}$$

(2)

and its complement, the probability that one or more crossovers have occurred in the interval $$D$$, is given by Equation (3)

$$p_{>0} = 1 - e^{-\lambda D}$$

(3)

Since for 1 or more crossovers, the recombination frequency $$\theta$$ is always 0.5, it can be expressed by Equation (4) in terms of physical distance as

$$\theta = 0.5 (1 - e^{-\lambda D})$$

(4)

from which distance is obtained from the observed recombination frequency as shown in Equation (5)

$$D = -\frac{\ln(1 - 2\theta)}{\lambda}$$

(5)

We now have expressions relating the experimental observation ($$\theta$$) to the underlying physical cause (the distance between the markers), by assuming a model in which crossovers occur randomly and independently of each other. The relation above between physical distance and $$\theta$$ is known as the “Haldane mapping function”. The units of distance are the mean number of crossovers which have occurred between the markers and is not bounded, whereas $$\theta$$ is bounded in the interval [0, 0.5], and is a good measure of distance only for small values. It is now known that crossovers occur on average every 100 Mb in the human genome, and every 200 Mb in the mouse genome, giving $$\lambda = 0.01 \text{ Mb}^{-1}$$ in human, and $$\lambda = 0.005 \text{ Mb}^{-1}$$ in mouse.

The two domains of $$\theta$$ and $$D$$ are different: $$\theta$$ is a frequency, is dimensionless, and lies in the range [0, 0.5]. $$D$$ is a distance measure, has units of mean number of crossovers, and is not bounded. Thus $$\theta$$ is not additive, whereas $$D$$ is, and in general $$\theta$$ should not be used as a measure of distance, but first converted to the additive distance measure using Haldane’s mapping function.

The assumption that crossovers occur randomly and independently is now known not to be strictly true, since the occurrence of a crossover at one location can inhibit formation of crossovers in its vicinity, a phenomenon known as “interference”. Therefore physical distances between close markers are underestimated. Also, some regions of the genome are known to be more susceptible to crossovers. Recombination frequencies in these “recombination hotspots” overestimate true physical distance. However, the basic assumption does provide a means of relating recombination frequency to physical distance which is valid over a large range of distances, and relates directly to subsequent analytical methods developed for RH mapping.

### 3.2 Strength of Linkage in Radiation Hybrid Experiments

The RH experiment is another means of detecting “linkage” between genes. Here, the strength of linkage is detected by measuring the degree of disruption between genes induced by controlled radiation-induced chromosome breaks, and counting the number of “offspring”, in this case human–rodent hybrid cells which retain a fraction of the resulting chromosomal fragments. The principle is that the closer two markers are together on the genome, the less likely it is that they will be separated by X-rays. Therefore markers close to each other show highly correlated patterns of retention across the cells of the hybrid panel. Again, breaks are assumed to occur randomly and independently. This assumption appears to be valid in the case of RH mapping, although there are some reports that certain regions of the genome are more susceptible to breakage than others. However, we will not consider this. In contrast to determining which parent the genetic material in the offspring originates from, the experiment is to determine presence or absence of pairs of markers in a number of independent clones which retain fragments. The average retention frequency of a marker across the panel is the frequency of hybrids retaining the marker, lies in the range [0, 1], and differs from panel to panel. This is in contrast to genetic mapping, in which the probability of retaining a gene from one particular parent is always 0.5. This adds an additional level of complexity to the analysis of an RH experiment.

We define formally here the “breakage frequency” as the probability that two markers have been separated by radiation, i.e. the probability that 1 or more breaks have occurred between them. If the physical distance between them is $$D$$ and breaks occur at a rate $$\lambda$$, the breakage
frequency $\theta$ is determined by the Poisson distribution, and is given by Equation (6)

$$\theta = 1 - e^{-\lambda D}$$  \hspace{1cm} (6)

from which Equation (7) gives the distance obtained

$$D = -\frac{\ln(1 - \theta)}{\lambda}$$  \hspace{1cm} (7)

The normalizing rate factor $\lambda$ enables conversion of distances in terms of mean number of breaks to other units, e.g. Mb. As in meiotic mapping, the two domains of $\theta$ and $D$ are different. Here, $\theta$ is the probability, lying in the range [0, 1], that a pair of markers have been separated by a break, whereas $D$ is the number of breaks that occur on average between them, and its range is not bounded.

The problem then is to estimate $\theta$ between two markers from the results of an RH experiment, which comprise the numbers of hybrids typed AB, Ab, aB, and ab for all pairs of markers A and B (Figure 2). When markers are so close that they are never broken apart, A and B are always found on the same fragment which can either be retained by a hybrid cell, which will then be typed AB, or not retained (hybrid is typed ab), that is $p_{AB} = p_A = p_B$, and only concordant classes AB and ab are observed. If the breakage frequency is 1, A and B are always on different fragments, and assuming that fragments are retained independently, the retention of markers A and B will also be independent, i.e. $p_{AB} = p_A p_B$.

For intermediate values of $\theta$, the numbers of hybrids typed AB arise from dependent retention of A and B on the same fragment and independent retention on different fragments (Figure 3). The estimate of $\theta$ is therefore not as simple as for meiotic recombination-based mapping.

In the following section it is useful to remember that the experimental observations, the numbers of hybrids typed AB, Ab, aB and ab for each pair of markers, are the result of two separate processes: (1) the fragmentation of chromosomes by X-rays; and (2) random retention of a subset of these fragments in a series of independent hybrid cells, which are then subsequently typed.

### 3.3 Estimation of $\theta$ by Goss and Harris (1975)

In the original Goss–Harris radiation-fusion experiment,\(^1\) the co-retention of markers with one selected marker was measured by counting their co-occurrence in a series of independent samples (human–hamster hybrids). If the marker was separated from the selected marker by a “segregation event”, i.e. chromosomal break, it was lost from the hybrid. Then $\theta$ is obtained directly from the frequency with which the selected marker occurred without the second marker as shown in Equation (8)

$$\theta = \frac{Ab}{N}$$  \hspace{1cm} (8)

The distances of all markers from the selected marker were measured as $D = -\ln(1 - \theta)$, and the relative order of markers was inferred from these distances.

In a second experiment,\(^3\) the restriction that markers be linked to a selectable marker was removed, by using...
human–mouse hybrids which were known to retain human chromosomal fragments in the absence of any selective pressure. This type of hybrid therefore allows mapping in any region of the human genome. The estimate of \( \theta \) using this panel became more involved, since the observation of two markers in a single hybrid could be due to both dependent coretention on the same fragment and independent coretention on two different fragments. They examine the likely composition of fragments of different types (\( AB \) together, \( A \) and \( B \) on separate fragments) in a hybrid observed to contain both \( A \) and \( B \). The frequency with which individual fragments of whichever type are retained in the hybrid was estimated from the data as Equation (9)

\[
r = \frac{r_A + r_B}{2}
\]

where \( r_A \) and \( r_B \) are the frequencies with which \( A \) and \( B \) are observed in the clones. The frequency of clones showing discordant expression of \( A \) and \( B \) (the frequency of clones expressing either \( A \) or \( B \) but not both) is then given by Equation (10)

\[
r_{\text{discordant}} = 2r(1-r)\theta
\]

If \( A \) and \( B \) were originally on different chromosomes then \( \theta = 1 \), and Equation (11) gives

\[
r_{\text{discordant}}^{\theta=1} = 2r(1-r)
\]

It follows in Equation (12) that

\[
\theta = \frac{r_{\text{Ab}} + r_{aB}}{r_{\text{discordant}}^{\theta=1}}
\]

i.e.

\[
\theta = \frac{r_{\text{Ab}} + r_{aB}}{2r(1-r)}
\]

Equation (13) when \( r \) is expanded gives Equation (14)

\[
\theta = \frac{r_{\text{Ab}} + r_{aB}}{r_A + r_B - (r_A^2 + r_B^2)/2}
\]

The authors express the relation between breakage frequency and distance as \( D = -\ln(1-\theta) \) using the Poisson distribution, from the assumption of random and independent breaks. Central to this analysis is the estimate of frequencies of retention of different fragments, which is observed only indirectly through the retention of markers. The significance of linkage was measured from the \( \chi^2 \) statistic with one degree of freedom.

### 3.4 Estimation of \( \theta \) by Cox et al. (1990)

The Goss–Harris mapping technique was revisited and modified, and the technique was named “RH mapping”. Analytical expressions were introduced for estimating \( \theta \) from the number of discordant clones, along similar lines to the formulation of Goss and Harris. The authors also estimate the frequency of retention of different fragments. Their reasoning is as follows. The observed marker segregation could be defined in terms of four unknowns: \( \theta \), \( p_A \), the probability of retaining a fragment containing \( A \) but not \( B \), \( p_B \), the probability of retaining a fragment containing \( B \) but not \( A \), and \( p_{AB} \), the probability of retaining a fragment that contains both \( A \) and \( B \).

The fraction of all hybrids retaining marker \( A \) but not marker \( B \) is represented in Equation (15) in terms of these parameters as

\[
\frac{A^+B^-}{N} = \theta p_A (1 - p_B)
\]

Similarly, Equations (16–18) give

\[
\frac{A^-B^+}{N} = \theta (1 - p_A) p_B
\]

\[
\frac{A^+B^+}{N} = (1 - \theta) p_{AB} + \theta p_{ABB}
\]

\[
\frac{A^-B^-}{N} = (1 - \theta)(1 - p_{AB}) + \theta (1 - p_A)(1 - p_B)
\]

Using just the expressions for \( Ab \) and \( aB \) gives Equation (19)

\[
\theta = \frac{p_{Ab} + p_{aB}}{p_A + p_B - 2p_{AB}}
\]

But as the authors state, it is not possible to estimate \( p_A \) or \( p_B \) from the observed data, since the experiment types hybrids for presence or absence of markers, not for presence or absence of fragments of certain types (\( AB \), \( A \), or \( B \)). They suggested using the observed frequencies of markers \( A \) and \( B \) (\( r_A \), \( r_B \)) as estimates of the unmeasurable quantities \( p_A \) and \( p_B \). The expression for \( \theta \) can then be given by Equation (20).

\[
\theta = \frac{r_{\text{Ab}} + r_{aB}}{r_A + r_B - 2r_{AB}}
\]

The use of \( r_A \) as an estimate of \( p_A \) was justified by observing that these numbers, when substituted into Equations (15) and (16), gave ratios of the discordant types \( Ab/aB \) that were not significantly different from the observed ratios. But \( r_A \) is the total retention of marker \( A \) whether or not it is on a separate fragment to \( B \), and therefore overestimates \( p_A \) by the frequency with which \( A \) occurs together with \( B \) on the same fragment.
(Figure 3). $p_B$ is similarly overestimated. Therefore the second term of the right-hand side of Equation (15) over-contributes to the estimate of $A$, and the third term under-contributes. These effects might therefore cancel each other out, giving the observed approximate agreement with the data. However, their final expression can be derived by other means, and it can be seen that it is identical to that of Goss and Harris, if the equality $r_A r_B = (r_A^2 + r_B^2)/2$ holds. This is the case when $r_A = r_B$, since Goss and Harris estimated only one fragment retention frequency as the average of the retention frequencies of the two markers.

Cox et al. also use the assumption of random and independent occurrence of chromosome breaks to relate $\theta$ to physical distance, $D = -\ln(1 - \theta)$, i.e. the mapping function derived above, but without the “rate” parameter $\lambda$. The units of distance are therefore “mean number of breaks”. They define a model of unit distance, the centiray (cR) which is equivalent to $D = 0.01$, by analogy with the centimorgan in meiotic mapping. The rate parameter is introduced as a subscript corresponding to the dose; 1 cR1000 = 0.01 breaks at a dose of 1000 rad, 1 cR8000 = 0.01 breaks at a dose of 8000 rad. The use of the mapping function converts breakage frequency to number of breaks, but requires some calibration for panels constructed with different X-ray doses.

The significance of the estimated breakage frequency was expressed as the likelihood of obtaining the observed data, given the model of fragment retention:

\[
L_\theta = [(1 - \theta) r_{AB} + \theta r_{AB}]^{AB} \left[ \theta r_{AB} \right]^{\text{Ab}} \\
\times \left[ \theta r_{AB} \right]^{\text{Ab}} \left[ (1 - \theta) r_{ab} + \theta r_{ab} \right]^{\text{Ab}}
\]

where $r_{AB}$ is an estimate of $p_{AB}$, the probability of retaining a fragment containing $A$ and $B$ together, estimated as $r_{AB} = \{(A^-B^+)/T - \theta r_{AB}\}/(1 - \theta)$. This was compared with the likelihood expected if $\theta$ were 1 (markers completely unlinked) to give a likelihood ratio of linkage versus nonlinkage.

3.5 Estimate of $\theta$ Directly from the Observed Marker Retention

We tried a different approach, choosing not to model the unobserved probability of retaining different types of fragment, but to use only the observed data, i.e. the frequencies of retention and coretention of markers to estimate the expected frequencies of the discordant hybrid types $A B$ and $aB$.\(^{12}\) We reasoned as follows, using only the two most basic assumptions of the RH experiment: random and independent occurrence of breaks, and random and independent retention of the resulting fragments.

For a hybrid typed $A B$, marker $A$ is necessarily on a different fragment to $B$. The probability of retaining a fragment that contains just $A$ is the product of the probabilities of two independent events, retention of $A$ and retention of $A$ separate from $B$. The probability of retaining $A$ is estimated from the data as $r_A$. The probability that the retained fragment contains $A$ and not $B$ is $\theta$, since the fraction of all fragments containing $A$ but not $B$ is $\theta$, by definition of $\theta$ as the frequency with which $A$ is separated from $B$. The probability of retaining $A$ on a separate fragment to $B$ is therefore $\theta r_A$. The probability of not retaining $B$ in any single hybrid in the panel is estimated from the observations as $1 - r_B = r_0$. Assuming independent retention of fragments, the expected frequency of the hybrids typed $A B$ is $p_{AB} = \theta r_A r_B$, and similarly, $p_{ab} = \theta r_a r_B$. The total expected frequency of the discordant classes is then $\theta(r_A r_B + r_a r_B)$. Equating the expected frequencies with the observed frequencies $r_{AB}$ and $r_{ab}$ gives an estimate of $\theta$, as shown in Equation (21), which uses the frequency of the discordant types ($r_{AB}$, $r_{ab}$), and individual marker retention frequencies ($r_A$, $r_a$, $r_B$, $r_0$).

\[
\theta = \frac{r_{AB} + r_{ab}}{r_A r_B + r_a r_B}
\]  

Here we observe that substituting $r_0 = 1 - r_A$ and similarly for $B$ in Equation (21) we obtain Cox’s expression (Equation 20), but obtained using only the observed frequencies and not requiring any substitution of unobservable frequencies. It needs no model of fragment retention other than that fragments are retained randomly and independently. A more detailed formulation based on information theory, and using additionally the frequencies of the discordant types, was described,\(^{12}\) and mapping tools based on these measures are available on the Web.

Distance was obtained from $\theta$ using the mapping function $D = -\ln(1 - \theta)$, assuming that breaks occur randomly and independently. The variance of the distance estimate was calculated from the law of errors of functions\(^{13}\) as Equation (22)

\[
\sigma^2(D) = \left\{ \frac{\partial}{\partial \theta} \left[ -\ln(1 - \theta) \right] \right\}^2 \sigma^2(\theta)
\]

which simplifies to Equation (23)

\[
\sigma^2(D) = \frac{\theta}{(1 - \theta)N}
\]

The variance is 0 when $\theta = 0$, $D = 0$, and $\infty$ when $\theta = 1$, $D = \infty$, as expected. This expression for the variance is useful for other analytical procedures such as weighted leastsquares fitting.

If the denominator of Equation (21) is replaced by the expression of Goss and Harris (Equation 11), for their estimate of the frequency of retention of fragments
containing A or B, we get Goss and Harris’s expression for the breakage frequency. However, this requires that the retention frequencies of A and B are equal, which is not generally true.

The significance of linkage we measured as the probability of the χ² statistic for a 2 × 2 table

$$\chi^2 = \sum_{XY} \frac{(N_{xy} - n_{xy})^2}{n_{xy}}, \quad X \in \{A, a\}, \quad Y \in \{B, b\}$$  \hspace{1cm} (24)

where $N_{xy}$ are the observed numbers of the different classes, and $n_{xy} = N_x N_y / N$ are the expected numbers if the markers were retained independently. The statistic measures the probability that the observed numbers of the four hybrid types AB, Ab, aB, and ab could have been obtained if A and B were always retained independently on different fragments ($\theta = 1$). The probability of the observed χ² is obtained from the incomplete β function.\(^{(14)}\) Small values for this probability indicate that it is unlikely that the observed distribution could be obtained by independent retention of A and B, and is therefore a likelihood ratio for nonlinkage versus linkage. Its negative logarithm is exactly equivalent to a lod score for linkage. We used the χ² statistic to obtain pairwise lod scores between markers.\(^{(12)}\)

3.6 Estimate of θ Using Maximum Likelihood

The requirement for estimates of the frequencies of retention of different fragments containing A and B on the same fragment used by Cox et al.\(^{(6)}\) prompted further work to estimate these frequencies by other means, since it now seemed that fragment retention had to be estimated in order to estimate θ. These other methods are now the basis for several software packages.

One means of estimating fragment retention frequencies was maximum likelihood (ML) used by Boehnke et al.\(^{(15)}\) ML methods had previously been used in genetic mapping.\(^{(16–22)}\) Where map distances were optimized to maximize the probability of the observed data. They were again applied in the field of RH mapping.\(^{(13)}\) Application of ML methods involves first constructing a model of the process assumed to be occurring, and estimate the values of the parameters by maximizing the likelihood of the data, given the model parameters. Parameters to ML models are breakage frequencies between all pairs of loci, and retention frequencies of different-sized fragments containing more or fewer markers on the same fragment depending on the fragment size. A breakage frequency $q_i$ is the probability that a break occurs between markers $i$ and $i + 1$. The retention probability $p_{ij}$ is the probability that a fragment containing loci $i$, $i + 1$, ..., and $j$ is retained in a RH. Trial interlocus distances are included in the calculation until a distribution of breaks across each chromosome is obtained that maximizes the likelihood of the observed distribution of markers across all hybrids in the panel. Likelihood methods therefore estimate distances between markers, and attach a likelihood to a given order of markers. ML methods require a means of scanning through the $N! / 2$ possible orders to optimize the model. Boehnke et al. used Expectation maximization.\(^{(23)}\)

The number of parameters that are adjusted is large: for $N$ markers, there are $N(N - 1) / 2$ different probabilities of retaining each different pair of markers on the same fragment. This makes ML computations expensive. To reduce the computational burden, Boehnke et al.\(^{(15)}\) restricted the ways in which fragment retention $p_{ij}$ was parameterized in the model to a small number of classes. These were (1) the equal retention frequency model, which assumes that all fragments containing all different pairs of markers were retained with equal probability, (2) moving-average model, in which the retention probability is the average value of the retention frequencies of all markers on the fragment, (3) Markovian models, chosen for the availability of rapid computational treatments for Markov chains, (4) centromeric or telomeric model, in which a fragment containing the centromere is retained with one constant frequency which is higher than that for all other fragments that do not contain the centromere, and (5) the left-endpoint model, in which the retention frequency is chosen to be the retention frequency of the marker closest to the centromere. The last two models were introduced since it was observed that marker retention probabilities for the Cox et al.\(^{(6)}\) 21q RH data decreased with increasing distance from the centromere.

The models therefore have the capacity for becoming extremely complex, and it is worth remembering here what is actually occurring. Retention frequencies of different fragments are chosen on the basis of their assumed location on the chromosome, and subsequently inter-marker distances are optimized to maximize the likelihood of the data. However, the normal case in mapping is that at the outset, there is no knowledge of chromosomal location. Determination of location is the aim of a mapping experiment, and yet assumed values are being used in ML methods prior to determining the location. Also, the restriction of fragment retention probabilities discards the experimentally observed frequencies of retention of individual markers. Despite these issues, ML methods form the basis of one of the most widely used software packages, RHMAP,\(^{(15,24)}\) which has been used effectively in many mapping projects. Walter and Goodfellow\(^{(6)}\) note that choice of different retention frequency models has little significant effect on the final maps generated by ML methods.
3.7 Methods for Determining Order

The methods described above are used to estimate distances between pairs of markers, but not the relative order of more than two markers. For $N$ markers there are $N!/2$ possible orders, and the number of possibilities increases rapidly with the number of markers. Efficient means are needed for identifying the best order(s) from the vast number of possibilities.

One means of determining order, but with no estimate of distances between adjacent loci, or of the likelihood of the computed order, is to find the order which minimizes the obligate number of breaks. This can be seen in Figure 1. Looking down a column in the middle and right-hand panels, the number of obligate chromosome breaks implied by a particular order of markers is the number of times down a column when the hybrid type changes from present to absent or vice versa, since each such discontinuity must be due to a chromosomal break between the flanking markers. The number of breaks in the correct order in the middle panel is 89, and in the randomized order, 759. It therefore seemed natural to find an order which minimized the number of breaks, since a random order has more breaks than the true order. This method was used previously in genetic mapping by permuting the order of markers to reduce the number of implied recombinants. Falk and Boehnke et al. describe the application of this method in RH mapping by permuting the linear order of markers. Thompson observed that the method had the effect of moving spurious double recombinants to the ends of a linear map. A similar effect in the RH experiment is to move error-prone markers to the ends of the map. Since the number of different orders of $N$ markers is large ($N!/2$), different methods of searching subsets of orders were suggested: stepwise locus ordering, simulated annealing, and branch-and-bound. Only branch-and-bound is guaranteed to find the minimum. The statistical properties of the minimum breaks method were examined by Barrett.

Another method of choosing likely marker orders from the vast number of possibilities was adopted in the program MultiMap/RADMAP. This method uses CRIMAP to calculate likelihoods for a given order, and a rule-based system using the AI language LISP to generate likely orders. The rules were constructed to replicate the process done manually by a human mapper, and were applied automatically to generate large numbers of likely orders. It increases the speed and efficiency of map construction. The best order chosen was the one with ML. Since the program reduced the time to generate maps, it also allowed exploration of different mapping approaches and heuristics used in map building. It was used in the construction of a map of human chromosome 13q containing 95 markers.

A third method for determining order directly from a distance matrix using the techniques of distance geometry (DG) is discussed below (section 3.10).

3.8 Genetic Analysis Workshop 7

In 1992, the Genetic Analysis Workshop 7 focused on RH and somatic cell hybrid mapping of chromosome 21 and new computational methods. This workshop demonstrated most of the methods currently used in the analysis of RH data, and provides a useful survey of the field. Nine groups analyzed the chromosome 21 RH data set using a variety of methods, mostly those recently developed by Boehnke et al., Bishop and Crockford, Boehnke, and Weeks et al. used different methods to find a marker order that minimized the number of obligate chromosome breaks. Bishop and Crockford enumerated all possible orders of eight markers. Boehnke used branch-and-bound to reduce the number of orders that need to be evaluated by eliminating groups of orders that had been shown to be suboptimal; Falk used simulated annealing to the same end. Falk also measured the coretention correlation ($r$) between all pairs of loci, and large values of the correlation indicated closeness of markers. The order of markers was permuted to maximize the sum of correlation between adjacent markers. The measure of distance was chosen to be $1 - r$. Weeks et al. estimated the probabilities that pairs of markers be transferred to the hybrid on the same fragment. They then also iterated over different locus orders, using simulated annealing, to find the order that maximized these probabilities between adjacent markers.

Likelihood methods were also demonstrated, using the framework developed by Boehnke et al. Chakravarti and Reefer assumed that all markers were retained with equal frequency, and built locus orders one marker at a time, and obtained the same order as Cox et al. Bishop and Crockford used both equal retention and centromerically preferred retention, and found that distances were very similar for the two different models. Green used the likelihood method CRIMAP of Lander and Green developed for the analysis of genetic mapping data, and obtained the same marker order as Cox et al. Lawrence and Morton used a multiple pairwise approach that had been used previously for genetic maps. They also obtained Cox’s marker order. Bayesian methods were used by Guerra et al., but it was found that the method was computationally very difficult, even for two or three loci.

3.9 Hidden Markov Models

A novel application of the statistical models known as hidden Markov models (HMMs) was demonstrated...
by Slonim et al.\(^{(41)}\) HMMs were used to estimate the likelihood of a map, when there is some uncertainty about typing. Graph algorithms are used to find sparse but reliable initial maps. The method is resilient to typing errors by assigning a priori false positive and negative rates, and allowing for such errors in the ML calculation. The method automatically detects markers that are likely to be error-prone.

### 3.10 Distance Methods

We adapted our previous method\(^{(42)}\) for constructing genetic (meiotic) maps using DG to obtain maps from RH data.\(^{(12)}\) This technique obtains coordinates from a measured distance matrix which gives distances on the derived map that optimally fit the observed distances. DG was developed in the field of nuclear magnetic resonance (NMR) to determine three-dimensional models of small proteins from observations of inter-proton distances obtained from NMR spectroscopy.\(^{(43–45)}\) Applied to RH mapping, the procedure was as follows:

1. Obtain a full \(N \times N\) distance matrix from the joint retention frequencies of all pairs of markers according to Equation (21), and their associated variance, Equation (23).

2. The distance matrix was first “smoothed” by replacing large imprecise distances with sums of smaller more precise distances. The variance estimate, Equation (23), was used as a measure of precision.

3. Obtain a “metric matrix” \(G\) from the smoothed distance matrix, which comprises the dot products of the vectors of each point to the origin\(^{(45)}\) according to Equation (25)

\[
g_{ij} = \frac{D_{ij}^2 + D_{jk}^2 - D_{ik}^2}{2}
\]

where \(D_{ij}^2\) is the squared distance of point \(i\) to the origin. This can be calculated without prior knowledge of the coordinates\(^{(43)}\) according to Equation (26)

\[
D_{ij}^2 = \frac{1}{N} \sum_{j=1}^{N} D_{ij}^2 - \frac{1}{N^2} \sum_{k=1}^{N} D_{jk}^2
\]

4. Coordinates are obtained for each of the points from the eigenvalues and eigenvectors of the metric matrix as Equation (27)

\[
c_{ij} = \sqrt{\lambda_i} w_{ij}
\]

where \(c_{ij}\) is the \(i\)th coordinate of the \(j\)th point, \(\lambda_i\) is the \(i\)th largest eigenvalue, and \(w_{ij}\) is the \(j\)th element of the corresponding eigenvector. Coordinates obtained in this way have been proved to be optimal\(^{(44)}\) in the sense that the spatial configuration of points so obtained minimizes the rotation error against the original distance matrix.

The method was applied initially\(^{(42)}\) to the chromosome 21 data,\(^{(5,7)}\) and subsequently\(^{(12)}\) to the RH data used to generate the human gene map.\(^{(46)}\) It generates orders directly from the calculated coordinates in a method with complexity \(O(N^3)\), i.e. the time taken for the computation to complete is proportional to \(N^3\) where \(N\) is the number of markers being considered.

### 4 Main Software Available

Many of the methods described above have been incorporated into software packages that can either be downloaded from the Internet, or are implemented as methods on mapping World Wide Web (WWW) servers to which data can be submitted, and the results returned in a Web browser or by e-mail. The main packages available are listed below, with the methods that they use.

#### 4.1 RHMAP

The minimum breaks method and the ML methods developed by Boehnke et al.\(^{(15)}\) and further by Lange et al.,\(^{(24)}\) have been incorporated into a package RHMAP. It is available at http://www.sph.umich.edu/group/statgen/software/.

#### 4.2 RHMAPPER

RHMAPPER\(^{(41,47)}\) is a software package for constructing RH maps, and was designed to map very large numbers of markers. It has other additional features: ML calculations using HMMs for analyzing diploid cells, such as those used in whole genomic mapping, and accommodation and detection of laboratory error. It is available at http://www-genome.wi.mit.edu/ftp/distribution/software/rhmapper/.

#### 4.3 Z-RHMAPPER

Soderlund et al.\(^{(48)}\) introduced modifications to RHMAPPER. The software is available at http://www.sanger.ac.uk/Users/cari/Zman.html.

#### 4.4 SAMAPPER

Stewart et al.\(^{(49)}\) used simulated annealing to order loci in the package SAMAPPER (http://www-shec.stanford.edu/Mapping/SAMapper/). It first obtains lod scores between all pairs of markers. The sum of lod scores between adjacent markers is then maximized by permuting the linear...
order of markers. The search through the \( N^{1/2} \) possible orders is directed by simulated annealing. Their model suggests that the solution with the maximum sum of lod scores is the most likely solution.

### 4.5 MultiMap/RADMAP

MultiMap/RADMAP\(^{30}\) is located at http://linkage.rockefeller.edu/multimap/. It automates the generation of alternative but likely orders using the results of likelihood calculations at previous stages, using rules coded in the AI language LISP. The authors recommend its use for large-scale mapping projects (>20 markers), or for the construction of many smaller maps.

### 4.6 Distance Geometry Map

The distance methods developed for RH mapping\(^{12,42}\) are available at http://www.oxmol.com/biolib/webmap.\(^{50}\) There are three modes of use: (1) copy and paste RH data for a series of markers, which are mapped with respect to each other; (2) find the \( N \) nearest markers to a named marker, and construct a locally accurate map in the vicinity of the reference marker rather than a whole chromosome; (3) enter the \( N \) nearest vectors to the marker vector from the specified RH panel, and map these markers relative to each other to build a locally accurate map including the novel marker.

### 5 PRACTICAL METHODS

Having reviewed the analytical processes involved in RH mapping, we now describe how data are obtained in the laboratory for subsequent analysis and determination of map location.

#### 5.1 General

One common use of RH mapping is to determine the location of an unknown (previously unmapped) marker on the genome. This is typically done by typing the marker on a RH panel for its presence or absence in each cell in the panel, and comparing the retention pattern with those of previously typed markers to find the closest matching markers and hence chromosomal region. The other major use is to map a series of markers with respect to each other, which involves typing each marker against a panel and mapping them with respect to each other.

#### 5.2 Obtaining a Radiation Hybrid Panel

RH panels are distributed by Research Genetics (http://www.resgen.com). There are three human panels (GB4, long range, low resolution; G3, mid range and resolution; TNG3, short range, high resolution), and single panels for mouse, rat, baboon, zebrafish and dog. For human mapping the choice of panel is determined by whether or not the approximate location of the marker is known previously. If not, it is best to use the long range, low resolution panel G4 to obtain an approximate location. If approximate location is known it is better to type on the higher resolution G3 or TNG4 panels, providing the marker density in the region is sufficiently high (see section 6).

#### 5.3 Typing Markers on the Panel

"Typing" a marker on a RH panel involves determining whether or not it is present in each of the individual component hybrids in the panel. Goss and Harris\(^{1–3}\) used enzyme assays to determine presence or absence of genes. Southern blot hybridization was used in the later experiments of Cox et al.\(^{5}\) Polymerase chain reaction (PCR) is now the preferred method, enabling small DNA samples to be detected in the hybrids. Several different protocols have been published on the WWW (Table 2). A typical RH typing gel from the Stanford Human Genome Center is shown in Figure 4. The presence of a marker in a hybrid is indicated by a PCR product which is visualized by agarose gel electrophoresis.

#### 5.4 Finding Close Markers

The results of the PCR are entered into the computer either directly as a string of 0s (absence) or 1s (presence), or via a clickable “typing frame” such as the one in Figure 5. This second method of data entry reduces possible errors in data input. The retention pattern of the marker on the panel is compared against the typings of all other markers that have been typed previously on the panel. These are generally available in the public domain on various web servers. Close markers have similar patterns of retention on the panel. Several mapping servers are available on the WWW, to which individual marker typings, or sets of typings for more than one marker, can be submitted. The servers return lists of nearest neighboring markers. The nearest markers to “marker, xyz” from mouse are shown in Figure 6. The closest, RH74155, is on mouse chromosome 3.

#### 5.5 The Map Location

The location of the new marker is then indicated by the known positions of the markers which it is close to. The

location of “marker,xyz” typed in Figure 5 is found to be close to a marker at 25.1 cM on the genetic map.

6 PROPERTIES OF RADIATION HYBRID PANELS

There are several RH panels available commercially, all of which differ in their means of construction, and therefore also in the properties they display. Here we discuss the variable properties of RH panels which must be considered for different mapping purposes.

6.1 Construction of Panels is under Experimental Control

Three parameters affect the results of a RH experiment: (1) the radiation dose used to construct the panel which determines the mean number of breaks in a unit physical interval ($\mu$); (2) the density of typed markers in unit distance intervals ($\lambda$); (3) the number of hybrids in the panel, which determines the significance of any detected linkage and the precision of the distance estimates to other markers. The conditions of the RH experiment can be varied at will, and should be considered when constructing new hybrid panels, or choosing existing panels, for specific mapping projects. Specifically, if a whole-genome map of a previously unmapped organism is to be made and the number of markers is relatively low, then a lower dose should be used to construct the panel. If on the other hand a very high resolution map of a localized region of the genome characterized by a large number of unique markers is required, then a panel should be constructed with a very high dose, e.g. the human TNG3 panel.

6.2 Available Panels

Table 3 summarizes the main properties of the commercially available RH panels from Research Genetics
The first panels to be constructed were for human (long-range G4\(^{(51)}\) medium-range G3\(^{(49)}\) short-range TNG3\(^{(52)}\)). There are now panels available for mouse, rat, dog, zebrafish, and baboon.

6.3 Effect of Marker Retention Frequency

In order for a marker to be maximally informative about its coretention with another marker, it should be retained in 50% of the cells in the panel. The amount of information that a marker can provide about its linkage to other markers can be quantified by the statistical entropy, 

\[ H_A = - \sum_{X \in \{A, a\}} p_X \log p_X, \]

where \(p_A \) is the retention frequency of the marker A and \(p_a \) of its allele a. The entropy is 0 for marker retention frequencies of 0 and 1.

6.4 Effect of Number of Hybrids on Resolution and Range

We define the resolution of a panel as the smallest breakage frequency that can be detected, and it is obtained when just one discordant hybrid is observed. As the number of hybrids in the panel is increased, the resolution increases. The range of a panel is the weakest linkage (largest value of the breakage frequency) that can be detected between adjacent markers with significance (e.g. with a lod score > 3). These values for simulated panels with the same radiation dose are summarized in Table 4. As the number of hybrids in the panel increases, so the resolution gets finer, and the range longer.
Figure 5 A “typing frame” originally developed for DG map at the BioLib site (http://www.oxmol.com/biolib/webmap). The user clicks the boxes which have been typed positive. “Submit” sends the data to the mapping server to find near neighbors.

6.5 Effect of Dose on Panel Range and Resolution

The X-ray dose used to fragment the donor chromosomes determines the size of the fragments generated: the higher the dose, the smaller the fragment size. Goss and Harris\(^{(1)}\) determined empirically the relationship between rate of breakage and dose \(D\) as \(D^{1/6}\). The exponent between 1 and 2 was interpreted as breakage involving one- and two-photon events. A compromise between two opposing properties of a panel must be struck when choosing the X-ray dose for construction of a particular panel.

\(\theta\) is the breakage frequency; \(Z(\theta)\) is the lod score for the observed breakage frequency, where \(Z(\theta) = -\log^{10}(P(\theta))\), and \(P(\theta)\) is the probability that the observed value of chi-squared for a \(2 \times 2\) (Equation 24) could have arisen by chance; \(D(R)\) is the distance (in units of mean number of breaks) between a pair of markers corresponding to the breakage frequency \(\theta\), calculated from Equation (7), where \(l = 1\).

Figure 6 Results of the search for “marker.xyz” having the retention pattern on the mouse T51 panel shown in Figure 5, and boxed in red here. The nearest neighbors are ranked according to the number of type matches across the panel. The histogram to the right of the retention patterns is the lod score of linkage, calculated as the negative log of the \(\chi^2\) probability for the \(2 \times 2\) joint retention frequency table. The chromosome to which the matching markers have been assigned is shown at the far right. The unknown marker is linked most strongly to RH74155 at 25.1 cM on chromosome 3 on the mouse genetic map with a lod score of 20.8.
A higher X-ray dose increases the potential resolution of the panel, since breaks occur closer to each other on average. Such panels can resolve markers that are closer to each other on a chromosome. But the significance of linkage over longer distances is severely reduced, since it is more likely that different markers segregate independently of each other, i.e. the range is shorter. This is manifested as “holes” in the map. Clusters of linked markers separated by holes cannot be ordered with respect to each other. This can be alleviated either by making an RH panel with a larger number of hybrids, increasing the number of observed concordant hybrids, or by typing a larger number of markers on the panel, thereby reducing the average distance between adjacent markers.

A lower dose reduces the resolution of the panel, since it is less likely that near markers will be separated by X-rays. However, longer distances between adjacent markers can be spanned.

An example of this is the G3 panel, constructed with 8000 rad, which is useful for resolving close markers, but is not reliable for constructing whole genome maps, unless a very large number of markers is typed, and the GB4 panel, made with a dose of 3000 rad, which is excellent for making maps of whole chromosomes, in which the distance between adjacent markers can be as large as 1 Mb. A new very high resolution panel, TNG4, constructed with 50 000 rad, many new markers will have to be generated to maintain significant linkage across the panel with smaller chromosomal fragments.

6.6 Effect of Marker Density on Significance of Linkage

The strength of a map can be defined as the average strength of linkage between adjacent (closest) markers on the map. This is determined by the combination of the mean number of breaks (µ) and the mean density of markers (λ) on the map. The mean density of breaks between adjacent markers is defined in terms of µ and λ as \( \mu^* = \mu/\lambda \). The probability that adjacent markers are not disrupted by X-ray breaks is then \( p_0 = e^{-\mu} \), and its complement is \( \theta = 1 - e^{-\mu} \). Therefore, if the dose is high, or the density of markers is low, the linkage between adjacent markers is weaker and it is harder to build maps with confidence.

This was illustrated in the first human gene map, which was constructed from the combined mapping on the GB4 and G3 panels. For the GB4 panel, \( \mu_{GB4} = 0.04 \text{Mb}^{-1}, \lambda_{GB4} = 0.36 \text{Mb}^{-1} \), giving \( \mu_{GB4}^* = 0.11 \). The breakage frequency between adjacent markers on the GB4 panel is therefore \( \theta = 1 - e^{-0.11} = 0.10 \), which with an average retention frequency of 0.32 and 93 hybrids gives an average inter-marker lod score of 17.5. For the G3 panel, \( \mu_{G3} = 0.27 \text{Mb}^{-1}, \lambda_{G3} = 0.16 \text{Mb}^{-1} \), giving \( \mu_{G3}^* = 1.7 \). The breakage frequency between adjacent markers on the G3 panel is therefore 0.82, with a lod score of 1.0. This very low average significance of linkage between adjacent markers on the G3 panels explains why the G3 map has many “holes”, between which clusters of more strongly linked markers cannot be ordered with respect to each other. To avoid this problem on the even higher-resolution panel TNG3, constructed with 50 000 rad, many new markers will have to be generated to maintain significant linkage across the panel with smaller chromosomal fragments.

7 APPLICATIONS OF RADIATION HYBRID MAPPING

The first applications of RH mapping were ordering of several markers in defined regions of the genome. It was rapidly applied to data previously obtained from genetic studies of disease and of inheritance of polymorphic markers mapped by genetic linkage studies which had enabled construction of genetic maps of the human and mouse genomes.

7.1 Disease Gene Mapping

The technique of positional candidate cloning involves first identifying an area implicated in disease, then identifying all genes that are thought to be located in a similar region. These genes are designated “candidates” due to their chromosomal location, and are categorized according to the likelihood that they might contribute to the disease phenotype. An example of the application of RH mapping to positional candidate cloning is the disease multiple endocrine neoplasia type 1, MEN-1. The MEN-1 and bcl-1 disease loci were known to flank MEN-1; SEA was therefore designated a candidate gene for the MEN-1 locus. Many other disease regions identified by genetic studies have been mapped in a similar way: BRCA1, neurofibromatosis type 2, and Huntington’s disease.
7.2 Whole-genome Human Maps

In a similar way, the large number of genetic markers that had been mapped using meiotic techniques, were subjected to the complementary technique of RH mapping. The markers had previously been shown to be unique and had been typed in naturally occurring populations. They were freely available for mapping on the new RH panels. Gyapay et al. mapped 374 Genethon markers on the new GB4 panel, and found good agreement with the previous genetic maps. Stewart et al. accomplished a similar task with 5994 markers generated at SHGC typed and mapped using the G3 panel. The largest map of sequence-tagged sites (STSs) contained 15,000 STSs.

Earlier in the decade, it was proposed that sequencing of the entire human genome should be considered a practicality. Brenner proposed that a reasonable intermediate stage should be first to sequence only those parts of the human genome that were actually expressed in tissue (1%), to maximize earlier the biologically functional information in the human genome. This proposal resulted in a vast effort to sequence all human expressed-sequence tags (ESTs). It was soon apparent that the same underlying sequences were being measured independently by many different groups, and each many times. This prompted the construction of “UniGene”, whose aim was to cluster the individual EST sequences to the unique underlying gene that was being expressed. At the time, there were ~170,000 ESTs which were grouped into 49,625 clusters, of which 4563 (9%) corresponded to known genes. The current number of sequences in human UniGene is ~1.2 million, grouped in 75,000 clusters. Each gene is therefore represented by ~16 EST sequences on average, some genes being represented by many more.

Since most human genes are thought not to be polymorphic, it is not possible to map them using traditional genetic mapping techniques which detect different types of the same gene. RH mapping, in contrast, detects the presence or absence of sequences rather than sequence differences, and was therefore an obvious choice for mapping all human genes in a reasonable timeframe. An international consortium comprising 10 mapping centers was established, with the intention of mapping all UniGene clusters. Representative sequences from each of the clusters (usually the longest) were distributed amongst the consortium members for typing on the G3 and GB4 panels. Map construction was coordinated at the Sanger Center, and the final maps were distributed from the NCBI web site. The first “gene map” of the human genome was published in 1996, and showed the locations of more than 16,000 human genes. The latest release of this map contains 30,000 genes.

Figure 7 shows the locations of 46 markers on band 11p11.12 estimated to span 4.46 Mb of the total 3000 Mb comprising the human genome (0.15%). It contains 46 mapped markers, of which 29 are associated with UniGene clusters, and 7 of these clusters are associated via their gene symbols to the database of human genetic diseases and disorders, OMIM. OMIM provides links to MedLine (Table 2). The loci corresponding to the OMIM entries are: 133701 – exostoses, multiple, type II; EXT2; 162096 – neurite growth-promoting factor 2; NEGF2; 600623 – prostate cancer antimitastasis gene KAI1, leukocyte surface antigen R2, SAR2, antigen CD82, suppressor of antigenicity 6, prostate, ST6; R2 leukocyte antigen; 600811 – DNA damage-binding protein 2, DDB2; 171650 – acid phosphatase of tissues. The map has recently been updated and contains 40,000 UniGene clusters.

The genomic localization of a unique DNA sequence can therefore potentially be linked to data and literature relating to human disease, and can provide a rapid means of devising novel strategies for the alleviation
or elimination of the symptoms of disease. This is one of the hopes of the new science of “pharmacogenomics”.

7.3 Mapping Other Organisms

Genetic mapping studies of organisms other than human both predate and lag human studies. They predate human studies for two reasons: (1) genetic selection has been practiced for thousands of years on agricultural species (plants and livestock) to increase yield; and (2) the genetic basis for inheritance of characteristics was established primarily in nonhuman species. The results of genetic studies conducted on “model” organisms such as mouse and rat has also generated many variant phenotypes that resemble human disease phenotypes. They lag human studies since most attention following the development of modern molecular biology has been towards understanding malfunctions or disease phenotypes in man. However, the large-scale application of these techniques in nonhuman species is rapidly gaining pace.

The mouse provides many model systems for the study of human disease, so a dense genetic map is of great value. An RH panel for the mouse (T31) was constructed in 1996\(^{(72)}\) and enabled construction of the first genome-wide RH anchor map of a model organism\(^{(73)}\) containing 271 STSs. Markers were located on average 8.8 Mb apart, and contained some gaps which could not be bridged using the RH panel. Clusters of strongly linked markers were therefore ordered with respect to each other by anchoring on the genetic map. Mapping of ESTs on the mouse genome to a similar density as the human is in anchoring on the genetic map. Mapping of ESTs on the mouse genome to a similar density as the human is in progress.\(^{(74)}\) The current genetic map, containing \(~7000\) genes, is too sparse to allow successful application of the positional candidate cloning approach. The higher density RH map will allow mapping of many more genes.

Centers mapping the mouse genome are the Jackson Laboratories, the Whitehead Institute and the Wellcome Trust Mouse Genome Center (see Table 2).

Many genetic experiments have also been conducted on the rat, and the phenotypes are useful as model systems for the study of similar conditions in humans. A RH panel of rat has been constructed and a dense map containing 5255 markers was recently published.\(^{(75)}\) Another rat mapping project,\(^{(76)}\) coordinated at the Whitehead Institute, has currently mapped 4736 simple sequence length polymorphism markers. These new maps of rat have revealed large regions of similarity between the rat and mouse and human genomes, providing valuable data for comparative mapping between the organisms.

The zebrafish has become a useful model organism for the study of the early stages of development, due to the ease with which its phenotypes can be determined by microscopy. A zebrafish RH panel has been constructed\(^{(77-79)}\) and is being used for mapping cloned genes and ESTs which are candidates for developmental mutations.\(^{(79)}\) The RH map is being anchored to the genetic map.\(^{(80)}\)

An RH panel containing the entire dog genome has been constructed\(^{(81,82)}\) on which 552 markers have been mapped. The dog species comprises 300 breeds and therefore contains a vast amount of polymorphism, manifest in many different phenotypes, e.g. physical appearance, behavior, and pathology. It is therefore an excellent species in which to study the genetic basis of these traits. The aim is to integrate the RH map with the third generation linkage map through the 207 common markers.

RH panels have also been constructed for cat,\(^{(83)}\) pig,\(^{(84,85)}\) and cow.\(^{(86)}\)

7.4 Integrating Data

One of the major problems remaining is to integrate the vast amount of new mapping data with the existing knowledge of the genes themselves, their products, their functions and pathology. This was highlighted already in 1996\(^{(87,88)}\) as a current problem. Eight years previously, it had been suggested that map and sequence data should be linked by STSs.\(^{(89)}\) One locus would be represented by one STSs which has one DNA sequence. Weissenbach and Bentolila\(^{(87)}\) regret that this has not been adopted in practice. They identify many sources of the problem, one being the proliferation and growth of databases such as dbEST, dbSTS, UniGene and OMIM. The problem is particularly acute in mouse and rat mapping, where different data are stored at many different sites. Databases easily and rapidly lose synchronization. Weissenbach and Bentolila suggest that mapping information should be simultaneously submitted to all relevant databases via a standard form. This would also prevent unlinked duplications. A universally acceptable mechanism is not yet implemented. When it is, the potential of the RH technique for comparative mapping and functional genomics will be greatly increased.

8 CONCLUSIONS

RH mapping is now an efficient and fast means of locating unique DNA sequences on a genome, and many methods exist for analyzing results of new RH experiments. The underlying physical processes are assumed to be simple, and have been of enormous importance in the HGP, providing a framework on which to place the DNA sequences of clones covering the entire human genome. The RH technique is now indispensable in rapidly generating genome-wide maps of different species. It was used to generate the high-resolution framework on which
to locate the large stretches of human DNA which are being measured in the HGP. It is almost certain that after completion of the HGP, RH mapping will be similarly used in the sequencing of other large vertebrate genomes, particularly mouse and rat. The high-resolution mapping of these organisms is already under way. It is also likely that similar effort will be directed at determining the gross genomic structure of any other organism that is considered important. It is already active in genomes of agricultural importance. It is further possible that any of the ~1000,000 species on the planet will at some stage become abnormally hostile or abnormally beneficial. In these cases, RH mapping is a tool that can be used to investigate such species and characterize them at the genomic level, giving better understanding of their biological properties and effects.

1 Definitions

Landmark: a locus or site to be visualized, distributed across genomes. A landmark can be utilized as a genetic marker, which should represent the physical condition, such as copy number, of its flanking region.

Restriction landmark: a landmark which can be recognized by a restriction enzyme.

RLGS: a method for visualizing restriction landmarks as spots on a two-dimensional profile. RLGS visualizes more than 2000 restriction landmarks in a genome in one procedure. RLGS has many applications, such as making a whole genome linkage map and scanning the amplified or deleted loci in cancer.

RLCS: a cDNA visualization system in which RLGS is applied to display many cDNA species as two-dimensional gel spots. The intensity of each RLCS spot reflects the expression level of each corresponding gene.

DNA methylation: in higher organisms, methylation of cytosine residues is often observed in genomes, and DNA methylation generally associates with the gene expression.

Restriction landmark genomic scanning for methylation (RLGS-M): a method for scanning genome-wide methylation conditions. RLGS-M can survey both endogenously imprinted genes and potentially expressed genes, based on the correlation of DNA methylation with gene expression.

2 INTRODUCTION

In recent decades, international genome projects have been making great progress toward the determination...
of the sequence of genomic DNA and the full-length cDNA encoding its final protein products.\(^1\)\(^-\)\(^3\) In terms of the analysis of the genomic structure, the full DNA sequence – including all information encoded by DNA other than DNA modification (methylation) – is the final goal. To achieve this, much effort has been devoted to the development of DNA sequencing technologies to facilitate sequencing speed. In fact, recent advances in these technologies should enable the entire genome-wide sequencing – or at least the rough sketching of the genomic sequence – to be completed within a few years, even for human, mouse and other higher organisms whose genome size exceeds \(3 \times 10^9\) base pairs (bp). Once the genomic sequence and the full-length cDNA sequence have been determined, the diversity of genomes can then be analyzed by studying sequence variations, such as single nucleotide polymorphism (SNP).

The technologies for de novo mapping and sequencing of the genome are totally different from postsequencing technologies. In the initial sequencing project, the mapping and sequencing technologies should not require any pre-existing information concerning the genome-wide sequence. On the other hand, at the postsequencing stage, the existence of genome-wide sequencing information will allow us to design much faster and more accurate technologies to analyze the individual variations in a sequence which has already been determined. In other words, we can then use any region of the genomic DNA as a ‘landmark’, based on knowledge of the genome-wide sequence.

The concept of genomic scanning arose from the necessity to sketch out the framework of the genome, using appropriate technology to visualize landmarks distributed throughout the genome. In this context, a ‘landmark’ is defined as a locus or site to be visualized, distributed across genomes. However, different types of landmark are used for genomic scanning prior genome-wide sequencing. The landmarks used in the pregenome-wide sequencing stage (presequencing landmarks) should not require any a priori sequencing information. On the other hand, landmarks used subsequent to genome-wide sequencing (postsequencing landmarks) should be susceptible to much more rapid screening than those used in the presequencing stage, taking advantage of the fact that postsequencing technology can use landmarks already identified. Once the genomic sequence has been determined, oligonucleotides which hybridize at any given site on the genome and which amplify any region of the genome through PCR can be designed to single-base accuracy. In theory, oligonucleotide chips can be used to identify SNP at any site on the genome. However, even with the recent amazing improvements in sequencing technology, the sequencing of large genomes still requires enormous amounts of time, labor and financing, and at present the best that can be expected is that the human genome may be completely sequenced in the coming few years. Under the circumstances, with many genomes to be analyzed, a rapid genome scanning system for de novo mapping based on ‘presequencing landmarks’ remains essential, not only for mapping, but also for the sequencing itself.

The ideal landmark for genomic scanning should offer the following benefits: (1) robust landmark signals which can be detected under reproducible conditions; (2) high-speed (multiplex) scanning; (3) signals which facilitate measurement of landmark copy number; (4) simple procedures and robotization; (5) scanning field expandability; (6) applicability to any organism; and (7) exportability of both techniques and information to other laboratories. So far, three types of ‘presequencing landmarks’ have been used to scan the genome. The first, the DNA probe with unique sequence, was quantitatively and qualitatively visualized using the Southern blot method. Detection of landmarks results from the sequence-specific manner of DNA–DNA hybridization. PCR was developed as an alternative method for detecting a second sort of landmark. PCR is a technique for amplifying a region of several hundred base pairs, flanked by a pair of oligonucleotide primers. Here, too, the specificity of the signals depends on the specificity of hybridization of the primers to a unique genomic region.

Recently, our group introduced a new or third approach, termed the ‘restriction landmark’, in which each site recognized by a restriction enzyme can be utilized as a landmark. Based on this concept, we have developed a method of RLGS which can visualize restriction landmarks as spots on a two-dimensional profile.\(^4\)\(^-\)\(^5\) This method employs (1) direct end-labeling of genomic DNA digested with a restriction enzyme and (2) high-resolution two-dimensional electrophoresis. As a method, it provides an alternative, multiplex approach to genomic analysis using robust landmarks, based on the strict specificity of sequence recognition of the restriction enzyme.

RLGS is a very important innovation for the following reasons. First, it provides us with a most powerful and speedy tool for genome-wide mapping for any organism.\(^6\)\(^-\)\(^8\) RLGS can scan more than 2000 landmarks in a single procedure. Once DNA samples from the family tree of any organism have been prepared, all of the polymorphic spots can be used for very rapid genetic mapping. Even in sketching out the framework of a genome, a mapping approach based on presequence landmarks, such as restriction landmarks, is still generally much faster than genome-wide sequencing, and a map of these landmarks is very helpful for the genome-wide sequencing itself. Second, RLGS does not require any a priori sequence information, reducing the total cost of mapping. The
most salient characteristic of restriction landmarking is that the methylation state of the landmark can be reproducibly assayed if a methylation-sensitive enzyme is used as the landmarking enzyme. To scan the methylation state throughout the genome, RLGS is thus the most rapid method available. In particular, the methylation condition of CpG islands controlling the transcription of genes can be quickly screened using GC-rich restriction enzymes such as \textit{NotI} as the landmarking enzyme.

To sum up, both pre- and postsequence landmarks are essential for genome mapping and scanning, complementing each other. Here, we describe the RLGS process which allows restriction landmakrs to be surveyed throughout a genome, together with suggestions for its application.

### 3 GENERAL PRINCIPLES

#### 3.1 Restriction Landmark Genomic Scanning

RLGS is based on a new approach to scanning efficiently and visibly many restriction enzyme sites on the entire genomic DNA. In essence, two issues must be resolved to achieve such scanning. The first is how to label specifically the particular restriction sites as landmarks without incurring nonspecific labeling. The second is how to detect through one procedure as many landmark loci as possible. Owing to the high complexity of genomic DNA in higher organisms, it has previously been considered difficult to achieve specific end-labeling at particular restriction sites and to detect the labeled fragments by conventional gel electrophoretic analysis. For example, when six-bp-recognizing enzymes were conventionally used as restriction enzymes to analyze the genomic DNA of higher organisms, it was very difficult to separate and detect the labeled restriction enzyme sites as discrete gel spots, because of the huge number of restriction enzyme sites and the nonspecific labeling of damaged sites such as nicks, gaps and/or double-stranded breaks in genomic DNA. However, these problems have been overcome by adopting new eight-bp-recognizing restriction enzymes known as ‘rare-cutters’ so as to give an appropriate number of DNA fragments for separation, in addition to new types of dideoxy nucleotide analogs to reduce nonspecific labeling. There has also been the development of a high-resolution two-dimensional electrophoresis system which enables us to detect simultaneously a multitude of loci as gel spots with enhanced sensitivity. For RLGS, it is essential, of course, to prepare genomic DNA of high quality. Average length and damage such as gaps and nicks are significant considerations. Since contamination by short fragments of less than 10 kbp in length results in increased background noise, the DNA must be prepared carefully without enzymatic degradation, especially at the lysis step at which various kinds of endonucleases leak from the lysosome. Treatment with proteinase K is effective in curbing such degradation in DNA preparation, but more care must be paid to avoiding enzymatic degradation by nuclease than to avoiding mechanical degradation such as shearing.

Figure 1 is a schematic representation of the principles and procedure of RLGS. The DNA is treated step by step as follows.

#### 3.1.1 Blocking

When a fixed amount of genomic DNA is subjected to gel electrophoretic analysis, the copy number of the DNA decreases as the genome size increases. However, nonspecific labeling is independent of genome size. Hence the ratio of noise to meaningful signals increases with increased genome size. Such noise substantially hampers the detection of specific signals in the case of genome sizes in excess of $1 \times 10^8$ bp. Thus, damaged DNA sites such as nicks, gaps and/or double-stranded breaks must be blocked in advance to avoid nonspecific incorporation of the radioisotope. For this purpose, a blocking technique has been developed employing dideoxy nucleotide analogs such as dideoxy-$[\alpha$-thio] nucleotides with one sulfur atom substituted for an oxygen atom (Figure 2). The incorporation of the analogs protects the damaged sites from elongation which would cause nonspecific labeling, as well as from 3’ exonuclease attack at the same sites in the labeling step. These analogs are incorporated enzymatically by a DNA polymerase such as DNA polymerase I.

#### 3.1.2 Landmark Cleavage with Restriction Enzyme $E_L$

The sites for restriction enzyme $E_L$ are isotopically labeled as landmarks. It is important to consider how many landmarks are desirable for the efficient detection of as many gel spots as possible. The appropriate number of restriction sites for the landmarks is around 3000 (each restriction site gives two landmarks). This means that restriction enzyme $E_L$ must be chosen to give DNA fragments with an average length of 1 Mbp in the case of human and other mammalian genome DNA whose length is approximately $3 \times 10^8$ bp. Thus, enzymes that recognize eight-base or rare sequences are most convenient for use as restriction enzyme $E_L$. Table 1 lists representative restriction enzymes.

#### 3.1.3 Labeling of Restriction Landmarks

Different labeling procedures are adopted depending on the nature of the cleaved sites generated by the restriction enzyme treatment. For a 5’-protruding end, a filling reaction of $[\alpha$-$^{32}$P]dideoxyribonucleotide is carried out
with Sequenase® Version 2, whereas for a 3'-protruding (or blunt) end, labeling is done with terminal deoxynucleotidyl transferase (terminal transferase) which can add \([\alpha^{32}\text{P}]\)dideoxynucleotides at the 3' termini of DNA fragments.

3.1.4 Fragmentation with Restriction Enzyme \(E_M\)

Generally, for mammalian genomes, more than 3000 DNA fragments of 1 Mbp average length are generated by treatment with restriction enzyme \(E_L\), even when the
chosen enzyme is NotI, the eight-bp-recognizing enzyme known as ‘rare-cutter’. In this case, the DNA fragments are too large to separate by gel electrophoresis. To overcome the problem, treatment with restriction enzyme EM, whose recognition sites occur more frequently in the genome than landmark EL sites, is adopted. Restriction enzyme EM must be selected to give a suitable number of gel spots allowing the use of a high-resolution electrophoretic thin-layer gel with a range extending to more than 40 cm.

3.1.5 First Fractionation by Agarose Gel Electrophoresis

In high-resolution electrophoresis, the thickness of the first dimension (1st-D) agarose gel is important, because its resolution affects that of second dimension (2nd-D) electrophoresis. Either horizontal or vertical gels are suitable if the gel is thin or fine enough to separate more than 3000 landmarks electrophoretically.

3.1.6 Fragmentation of Labeled DNA with Restriction Enzyme EN

The agarose gel strip or gel cylinder used in 1st-D electrophoresis is treated in situ with restriction enzyme EN, whose sites appear even more frequently than restriction enzyme EM sites. Usually four-bp-recognizing enzymes are used as restriction enzyme EN, but six-bp-recognizing enzymes are also usable.

3.1.7 Second Fractionation by Polyacrylamide Gel Electrophoresis

The thickness of the second gel is determined by that of the first gel, as already noted. The first cylindrical gel or ‘noodle’ is connected to the 2nd-D polyacrylamide gel, which is also usable either horizontally or vertically. DNA fragments between 70 bp and 2 kbp are separable by this electrophoresis.

3.1.8 Autoradiography

The gel sheets are dried and autoradiographed.

3.1.9 Results

Figure 3 shows a representative result of RLGS, when NotI, EcoRV and HindIII are used as restriction enzymes EL, EM and EN. More than 2000 spots are clearly visible.

3.2 Restriction Landmark cDNA Scanning

RLGS is a powerful and efficient method for analyzing an entire genome. It enables us to visualize simultaneously many loci as gel spots. RLGS has proved to be powerful in various applications such as genetic mapping, detection of...
methylatable loci including imprinted loci and detection of aberrated loci in cancer cells.

RLCS is a novel cDNA visualization system in which RLGS is applied to display many cDNA species as two-dimensional gel spots. The principle of RLCS is essentially the same as that of RLGS, with the cDNA cleaved by restriction enzymes being labeled isotopically at the restriction sites and separated by high-resolution two-dimensional gel electrophoresis, followed by autoradiography. The preparation of cDNA species of a uniform length for each mRNA species is crucial for RLCS, just as the quality of DNA is crucial for RLGS. For this purpose, a specially designed oligo(dT) anchor primer which facilitates anchoring to mRNA at the upstream end of the poly(A) tail, and easy recovery by its biotin residue at the 5′ end, is used for cDNA synthesis. The primer also carries multiple restriction enzyme sites such as NotI, NruI, XbaI and SpeI. A representative primer is 3′-AMT15CCGCAGCGAGCTAGAT-CTTGATAG-biotin (M = A, G or C). Alternatively, an anchor primer with G, C or T instead of A at the 3′ end is also usable. Figure 4(a) and (b) is a schematic representation of the principles and sequential procedures of RLCS.

cDNA synthesized using reverse transcriptase and the anchor primer is enzymatically blocked by 2′,3′-dideoxyribonucleoside triphosphate (ddNTP) to prevent nonspecific labeling in the labeling reaction (steps 1 and 2 in Figure 4a). The cDNA is then cleaved by the first restriction enzyme E1 whose sites (L) are successively labeled as landmarks (steps 3 and 4). An enzyme that generates protruding cohesive 5′ termini is recommended for use as restriction enzyme E1 because its restriction sites are easily radiolabeled by DNA polymerase I. Such

---
an enzyme is also preferable for recovering target fragments from the gel spots when spot cloning is necessary. These labeled fragments are recovered using streptavidin-conjugated magnetic beads (step 5), and released from the beads by restriction enzyme NotI, whose site is included in the anchor primer (step 6). The recovered fragments, which must be uniform in length for individual cDNA species, are subjected to high-resolution two-dimensional gel electrophoresis as in the case of RLGS (Figure 4b). In practice, cDNA synthesis is carried out using several micrograms of poly(A)$^+$RNA and 1µg of the anchor primer. Double-stranded cDNA (0.2–0.3µg, 1000bp

![Figure 5](image)

**Figure 5** Representative RLCS patterns. Poly(A) RNAs were prepared from mouse liver (a), cerebral cortex (b) and cerebellum (c). For restriction enzyme cleavage both BamHI and BglII were used together as enzyme $E_L$, and HinII was used as enzyme $E_M$. 
average size) obtained from 1 µg of poly(A)^+RNA is usually treated with restriction enzyme E_L, followed by labeling, and subjected to 1st-D gel electrophoresis.

Figure 5(a–c) shows typical RLCS patterns resulting from gel electrophoresis of cDNA samples prepared from mouse liver and brain (cerebral cortex and cerebellum). Approximately 500 gel spots are detected for the liver, their pattern differing substantially from that of any brain region. More than 1000 gel spots are observed for the two brain regions (Figure 5b and c), their gel patterns being very similar but not identical. The differences in intensity have been confirmed (using conventional Northern analysis employing cloned spots as probes) to reflect the expression level of each transcript (Figure 6a and b).

Is this RLCS method sufficiently sensitive to detect even very rare mRNA species? As already described, in RLCS 0.2–0.3 µg of cDNA is applied to each gel. Since the average size of the cDNA is 1000 bp, the total copy number of the cDNA is calculated as 
\[
\frac{(0.2-0.3) \times 10^{-6}}{(6 \times 10^{12})} = (1.8-2.7) \times 10^{11}
\]

If the population of very rare mRNA species corresponds to 0.0001% of total mRNA, the cDNA copy number is calculated as 
\[
(1.8-2.7) \times 10^{11} \times 0.0001\% = (1.8-2.7) \times 10^8
\]

By comparison, in RLGS, 1 µg of genomic DNA, corresponding to 3 × 10^12 copies for mammalian genomes, is applied per gel, and is enough to detect a large number of gel spots. Even spots whose intensity is several times weaker than that of the major spot population are readily detectable. This means that even very rare mRNA species are detected by RLCS.

Hence, RLCS is a sensitive quantitative method that enables us to visualize more than 1000 cDNA species at once. However, the display of even more cDNA species as gel spots requires enhancement of the technique.

Recently, RLCS has been further improved and refined as follows. (1) The display of an increased number of gel spots has been demonstrated by using more than two RLCS gels and different restriction enzymes. However, the appearance of redundant spots proved problematic (redundant spots are spots corresponding to the same gene but appearing in two or more loci). To overcome this problem, the combination and order of application of the restriction enzymes are being examined. (2) Accurate priming of reverse transcription reactions using anchored oligo-dT primers has been examined under novel experimental conditions. Theoretically, cDNA species which have different 3' end sequences flanking poly(A) tails could be separately displayed on the different gels by using two different kinds of anchor primers with MN at the 3' end. Thus, cDNA having a GC sequence at the 3' end just upstream from a poly(A) tail should appear only when a GC anchoring primer is used. However, this has proved problematic in practice, because mispriming of the anchor primers causes a single cDNA to be observed in two different ‘windows’. To avoid mispriming, we successfully improved the results by performing the reverse transcriptase reaction at a higher temperature in the presence of trehalose and oligonucleotide blockers. By applying these two modifications, many more cDNA species can be displayed.

4 PROTOCOLS

4.1 Introduction

RLGS analysis comprises several steps: DNA extraction, landmark labeling, two-dimensional electrophoresis, spot analysis and spot cloning as described in section 2. Here, we elaborate on several aspects of the RLGS technique.

4.1.1 Choice of Restriction Enzymes, E_L, E_M and E_N

With various combinations of restriction enzymes, e.g. BssHII, EcoRV and HinfI, or PacI, BamHI and HinfI, RLGS can screen the physical conditions of the restriction landmarks of the entire genome. Here, we describe
the protocol for the set NotI, PvuII and PstI for screening deletion, amplification and methylation of the landmarks in the mammalian genome. The NotI recognition sequence, GCGGCCGC, is known to be generally located in the CpG islands, enabling us to screen efficiently amplification and deletion of potential transcriptional units, because almost all CpG islands generally locate in the upstream region of transcriptional units. Furthermore, since NotI is one of the methylation-sensitive enzymes, methylation conditions can also be screened.

4.1.2 DNA Extraction, Landmark Labeling and Two-dimensional Electrophoresis

As described in section 2, all procedures are optimized for producing a high-resolution profile with low background noise.

4.1.3 Apparatus for Two-dimensional Electrophoresis

RLGS uses specially designed apparatus manufactured by Biocraft Inc. (Tokyo, Japan) for both 1st-D and 2nd-D gel electrophoresis (Figure 7a and b). In 1st-D gel electrophoresis, an agarose gel noodle serves as the medium. Figure 8(a) and (b) shows the Teflon® tube used in the procedure, encased within an outer glass tube to maintain its shape. About 50 cm of agarose gel and slow electrophoresis facilitate the very detailed resolution of DNA fragments. The electrophoretic tank for the 2nd-D acrylamide gel electrophoresis is designed so that four gels can be processed at once (Figure 9a–d). The required acrylamide gels can also be made in this same electrophoresis apparatus, obviating the need to transfer gels.

4.1.4 Spot Cloning

The method used to recover landmark spots on RLGS gels is essential for further studies such as identifying the genes that may be associated with the landmark sites and determining their functions. Target DNA fragments electro-eluted from an RLGS gel can be directly cloned by ligation with an appropriate cloning vector when the genomic DNA of microorganisms of relatively smaller genome size (10⁶ – 10⁷ bp) – such as Staphylococcus aureus – is subjected to the RLGS system. However, in higher organisms like mice or humans,
NUCLEIC ACIDS STRUCTURE AND MAPPING

Figure 9 (a) Assembly of glass plates in 2nd-D electrophoretic apparatus. Four gel spaces, each 1 mm wide, are separated by five glass plates. (b) Adding acrylamide gel through Teflon® tubing at one end of the apparatus. Three holes, which serve to pass the electrophoretic current during the run, are temporarily sealed with 3 M Scotch tape. (c) Side view of the attachment of 1st-D agarose gel noodles to the 2nd-D polyacrylamide gel. The Scotch tape has been removed for electrophoresis.

which have a larger genome size of $3 \times 10^{19}$ bp, less than 0.75 attomoles ($7.5 \times 10^{-19}$) of target DNA fragments are available from an RLGS gel spot for each 1.5 µg of sample application, making it necessary to enrich the DNA fragments before cloning. In section 3.4 below, we introduce two methods for spot cloning, a PCR-mediated method and a restriction trapper-mediated method.

4.2 Preparation of Genomic DNA

It is important to isolate genomic DNA with as little damage as possible, because nicks and gaps cause nonspecific incorporation of radioisotopes in the labeling step, resulting in background noise. To avoid any damage, the critical technical point is to suppress DNase activity.

4.2.1 Materials and Reagents

Tris–EDTA (TE) [10 mM Tris-Cl, pH 7.5–1 mM ethylenediaminetetraacetic acid (EDTA)]; phenol–chloroform–isoamyl alcohol (PCI) (50:49:1), 0.1% 8-hydroxyquinoline, buffered with TE; lysis buffer (150 mM EDTA, 1% sodium dodecyl sulfate (SDS), 10 mM Tris-Cl, pH 8.0); proteinase K solution (Merck, Darmstadt, Germany) [10 mg mL$^{-1}$, dissolved in distilled water (DW)]; RNase A solution (Boehringer, Mannheim, Germany) (1 mg mL$^{-1}$ dissolved in DW, boiled for 15 min for inactivation of DNase); mortar; pestle; dialysis tube.

4.2.2 DNA Preparation

The mortar, pestle, spatula and aluminum foil are prechilled in liquid nitrogen (LN$_2$). A 2-mL volume of lysis buffer and 0.5 g of the tissue are frozen in LN$_2$ and wrapped in aluminum foil, after which the frozen tissue is crushed with a hammer. The tissue pieces are transferred to the mortar and ground into powder with the pestle. The ground tissue powder is transferred to the mortar and ground into powder with the pestle. The ground tissue powder is transferred to a 50-mL Falcon tube, to which is added 25 mL of lysis buffer and 150 µL of proteinase K solution. Quick but gentle stirring with the spatula gives a viscous sample. This mixture is incubated for 20 min at 55°C and, after chilling on ice, 25 mL of PCI are added, followed by gentle stirring with a rotator (25 rpm) for 30 min. The sample is then centrifuged at 3000 rpm for 30 min and the resultant aqueous phase transferred to a new Falcon tube. This PCI extraction should be repeated more than twice. After PCI extraction, the aqueous phase is transferred to a 50-mL Falcon tube, to which is added 25 mL of lysis buffer and 150 µL of proteinase K solution. This mixture is incubated for 20 min at 55°C and, after chilling on ice, 25 mL of PCI are added, followed by gentle stirring with a rotator (25 rpm) for 30 min. The sample is then centrifuged at 3000 rpm for 30 min and the resultant aqueous phase transferred to a new Falcon tube. This PCI extraction should be repeated more than twice. After PCI extraction, the aqueous phase is transferred to a dialysis tube and dialyzed overnight against TE. Following dialysis, the sample is transferred to a Falcon tube, to which is added 40 µL of RNase A solution, and then incubated for 2 h at 37°C. At this stage, the volume of the sample is about 30 mL. The sample is now divided into two Falcon tubes (about 15 mL each), to each of which 35 mL of ethanol are added, and the two are gently rotated (15 rpm) for 30–60 min to precipitate the DNA. After precipitation, the precipitates are retrieved and
transferred to an Eppendorf tube to which are added 300–500 µL of TE buffer (drying is not necessary) and then kept at 4 °C to dissolve the DNA. The concentration is adjusted to 1 mg mL\(^{-1}\).

Genomic DNA over 200 kb long can be recovered using this protocol. For checking the quality of the DNA, an aliquot portion is subjected to electrophoresis in 1% agarose gel. DNA fragments shorter than 20 kb should scarcely be observed under ethidium bromide staining (Figure 10). If a smeared image of fragmented DNA is seen, the samples are significantly damaged and should not be used for RLGS analysis.

4.3 Labeling of Restriction Landmarks

The labeling protocol is designed so that all reactions can be performed sequentially in a single tube. Manipulation is very easy, involving only the adding of reagents and mixing.

4.3.1 Materials and Reagents

DNA polymerase I (Toyobo); deoxynucleoside [α-thio] triphosphates (dGTP[α]S, dCTP[α]S) (Toyobo); deoxynucleoside triphosphates (ddGTP, ddATP, ddTTP, ddCTP [Toyobo]); [α-\(^{32}\)P]dGTP (3000 Ci mmol\(^{-1}\)) (Amersham); [α-\(^{32}\)P]dCTP (6000 Ci mmol\(^{-1}\)) (Amersham); NotI (Takara); PvuII (Toyobo); PstI (Takara); Scal (Takara); bovine serum albumin (BSA) (Sigma fraction V); Triton X-100; Sequenase\textsuperscript{®} Version 2.0 (USB, Cleveland, OH, USA); 10× high buffer (HB) [500 mM Tris-Cl (pH 7.4), 100 mM MgCl\(_2\), 1 M NaCl, 10 mM dithiothreitol (DTT)]; 10× medium buffer (MB) [100 mM Tris-Cl (pH 7.5), 100 mM MgCl\(_2\), 10 mM DTT, 500 mM NaCl]; 2.5× SH buffer (0.375 M NaCl, 0.25% Triton X-100, 0.25% BSA); pBSII solution [0.5 µg/8 µL pBlue-Script II (Stratagene, San Diego, CA, USA) in 1× HB]; pUC18 (0.5 µg µL\(^{-1}\) pUC18 in 1× MB); DTT.

4.3.2 Blocking of DNA

For blocking DNA, mix the following reagents:

<table>
<thead>
<tr>
<th>Reagent</th>
<th>Amount</th>
</tr>
</thead>
<tbody>
<tr>
<td>DNA sample</td>
<td>10 µg</td>
</tr>
<tr>
<td>10× HB</td>
<td>1 µL</td>
</tr>
<tr>
<td>1 M DTT</td>
<td>0.1 µL</td>
</tr>
<tr>
<td>10 mM dGTP[α]S</td>
<td>0.4 µL</td>
</tr>
<tr>
<td>10 mM dCTP[α]S</td>
<td>0.2 µL</td>
</tr>
<tr>
<td>10 mM ddATP</td>
<td>0.4 µL</td>
</tr>
<tr>
<td>10 mM ddTTP</td>
<td>0.4 µL</td>
</tr>
<tr>
<td>DNA polymerase I</td>
<td>0.5 µL</td>
</tr>
<tr>
<td>DW</td>
<td>to 10 µL</td>
</tr>
</tbody>
</table>

Mix gently, but completely, with pipeting (since DNA solution is very viscous, solutions must be thoroughly mixed). Incubate for 20 min at 37 °C for digestion and for 30 min at 65 °C for inactivating DNA polymerase I. All solutions except the sample and DNA polymerase I can be premixed and stored at –20 °C for use as blocking buffer.

4.3.3 Landmark Cleavage

Mix the following reagents:

<table>
<thead>
<tr>
<th>Reagent</th>
<th>Amount</th>
</tr>
</thead>
<tbody>
<tr>
<td>DNA sample (blocked)</td>
<td>10 µL</td>
</tr>
<tr>
<td>2.5× SH buffer</td>
<td>8 µL</td>
</tr>
<tr>
<td>NotI (10 U µL(^{-1}))</td>
<td>2 µL</td>
</tr>
</tbody>
</table>

Mix completely and incubate for 2 h at 37 °C for complete digestion. It is recommended that digestion be routinely checked for completion. For this purpose, transfer 2 µL of the mixture into another tube, add the control plasmid and incubate in parallel at 37 °C for 2 h.

<table>
<thead>
<tr>
<th>Reagent</th>
<th>Amount</th>
</tr>
</thead>
<tbody>
<tr>
<td>DNA sample</td>
<td>2 µL</td>
</tr>
<tr>
<td>pBSII solution</td>
<td>8 µL</td>
</tr>
</tbody>
</table>

After incubation, electrophorese with 0.8% agarose gel. When digestion is complete, only two clear bands should be seen. Observation of a 2.9-kb band indicates that digestion is only partially complete (Figure 11).

4.3.4 Landmark Labeling

After digestion is complete, add the following reagents for labeling the NotI landmarks. (At restriction landmarks generated by NotI, a radioisotopic nucleotide is incorporated with DNA polymerase I. Sequenase\textsuperscript{®}, one of the DNA polymerases, is better for suppressing background noise, because it lacks the 3’–5’ exonuclease activity.)

<table>
<thead>
<tr>
<th>Reagent</th>
<th>Amount</th>
</tr>
</thead>
<tbody>
<tr>
<td>DNA sample (landmark-cleaved)</td>
<td>18 µL</td>
</tr>
<tr>
<td>1 mM DTT</td>
<td>0.3 µL</td>
</tr>
</tbody>
</table>
Mix well by pipeting, and incubate for 30 min at 37°C.

In the case of 3' protruding and blunt ends, landmarks can be labeled with [α-32P]ddNTP by terminal deoxy transferase. (4)

4.3.5 Digestion with Restriction Enzyme E 

The second digestion is performed with PvuII. Add the following reagents to the sample tube:

DNA sample (landmark-labeled) 20.4 µL
1 mM ddGTP 1 µL
1 mM ddCTP 1 µL
100 mM MgCl2 1.2 µL
DW 4.4 µL
PvuII (10 U mL−1) 2 µL

Mix gently but completely by pipeting and incubate for 1 h at 37°C. All solutions except for the sample and PvuII can be premixed and stored at −20°C for use as the second digestion buffer. As in the case of landmark cleavage, use of an aliquot portion is recommended to check for complete PvuII digestion. For the purpose, 2 µL of the mixture are transferred to another Eppendorf tube and the circular pUC18 control DNA is added, followed by incubation for 1 h at 37°C (the same as for the sample) and then electrophoresis in 0.8% agarose.

Sample 2 µL
0.1 µg of pUC18 circular plasmid 8 µL

After incubation, the sample is subjected to electrophoresis in 0.8% agarose and checked for digestion bands. If the digestion is complete, only linearized plasmids of 2.7 kb can be observed (Figure 11).

4.3.6 Adjustment of Sample Concentration

A 2-µL volume of the labeled sample is placed in an Eppendorf tube, to which is added 100 µL of salmon sperm DNA solution and 100 µL of ice-cold 20% trichloroacetic acid (TCA). After incubation for 5 min on ice, the precipitate is collected by filtering the solution through a glass microfiber filter. The filter is washed with 9 mL of ice-cold 20% TCA and the radioactivity remaining on the filter is measured with a liquid scintillation counter. The concentration of the sample is then adjusted to 9000 cpm µL−1 by the addition of 6× loading dye (10) and the sample is stored until 1st-D electrophoresis at 4°C.

4.4 Two-dimensional Gel Electrophoresis

4.4.1 Materials and Reagents

All apparatus for both 1st-D and 2nd-D electrophoresis (Figure 7a and b) are manufactured by Biocraft (Tokyo, Japan), including the electrophoretic tanks, 1st-D gel holder (the glass support tube) and the Teflon® tubing.

10× 1st-D buffer (dissolve 242 g of Tris, 109 g of sodium acetate trihydrate, 42 g of NaCl and 23.4 g of EDTA disodium salt in 1.8 L of H2O and adjust the pH to 8.15 with acetic acid; adjust the volume to 2 L and send through a 0.2-µm filter or autoclave; the pH of the 1× buffer should be 8.0); 10× Tris–boric acid–EDTA (TBE) buffer (dissolve 1210 g of Tris, 770 g of boric acid and 75 g of EDTA disodium salt in H2O and adjust to 20 L); dye solution (0.25% bromophenol blue (BPB), 0.25% xylene cyanol in TE without glycerol); 0.8% agarose gel solution [dissolve 0.8 g of SeaKem® GTG agarose (FMC Inc.) and 5 g of sucrose in 1 L]; 5% 2nd-D acrylamide gel solution (dissolve 96.7 g of acrylamide, 3.3 g of methylenebisacrylamide, 1.3 g of ammonium persulfate and 200 mL of 10× TBE in DW and adjust to 2 L with DW; add 800 µL of N,N,N’,N”-tetramethylethlenediamine (TEMED) just before use to solidify the gel).

4.4.2 Preparation for First-dimensional Electrophoresis

Gel holders for the agarose gel noodles are made from Teflon® tubing and glass support tubes, as shown in Figure 12. The hard glass outer cover to the Teflon® tubing not only protects the fragile agarose gel from damage but also makes handling easier. Because the inside diameter of the glass tube is slightly larger than the outside diameter of the Teflon® tubing that will be inserted, one end of the glass tube must be beveled and narrowed by heating and shaping to tightly fix the Teflon® tubing. As shown in Figure 12, the top of the Teflon® tubing is cut at an angle of about 15°, passed through the glass support tube from the unbeveled end and then pulled out about 2 cm at the top using pliers. It
is necessary to ensure that the upper part of the Teflon® tubing is stationary before it is trimmed to leave about 2 mm at the top and about 1 cm at the bottom. Next, the tip of a flanging tool is heated and the top of the tubing pushed on to the heated tip. After a few seconds, the tool is removed and the top of the tubing is pressed against a flat smooth surface such as a sheet of glass.

A 0.8% agarose gel is used to separate DNA fragments in 1st-D electrophoresis. As shown in Figure 13, the 0.8% agarose dissolved in the 1st-D buffer is gradually sucked up into the tube until it reaches a height of 59 cm, that is, about 1 cm from the top, using a syringe fitted with a three-way stopcock. The three-way stopcock is immediately closed and the tube left until the gel solidifies, after which the stopcock is opened and the syringe–stopcock unit carefully removed.

A 350-mL volume of 1× 1st-D buffer is added to the cathodal bottom of the tank and the gel holders are fitted into the anodal top, after which the tank is filled with another 250 mL of 1× 1st-D buffer. Nine samples can be run simultaneously on the described apparatus.

4.4.3 Preparation of Second-dimensional Acrylamide Gel

The 2nd-D electrophoretic tank is assembled as shown in Figure 9(a–d). After sealing the side holes with 3M Scotch tape, the 2nd-D acrylamide gel solution is poured through the side Teflon® tubing until it reaches the top of the glass plates. A 3-mL volume of 2-butanol is gently dropped on top of the gel, which is left to stand for about 2 h. Just before the 2nd-D electrophoresis, the 3M Scotch tape is peeled off and the 2-butanol washed out with 1× TBE.
4.4.4 Running of First-dimensional Gels

After the gel noodles have been left at room temperature for about 1 h, they are ready for a run. A 15-µL volume of the labeled sample (containing about 140 000 cpm of labeled DNA) is applied to the gel. Electrophoresis is carried out at a constant voltage of 180 V for about 14 h, at which time the BPB dye reaches 50 cm.

4.4.5 Extruding and In Situ Restriction Enzyme Digestion

When the electrophoresis is completed, the anodal tank buffer is removed with an aspirator and the gel holders are taken out. The gel noodles can be expelled from the holders using a 1-mL syringe with a cut-off yellow Eppendorf tip. The gel noodles are cut 3 cm from the end, at the 500 bp point, and marked with BPB dye solution (0.01%) so as to make it easy to work with them. The noodles (about 57 cm in length) are soaked in 50-mL Falcon tubes containing 40 mL of 1× HB (Figure 14a and b) for 10 min. The buffer is changed and the noodles are soaked again for 10 min to reach complete equilibrium.

Digestion is carried out in situ in the Teflon® tubing. For this purpose, the equilibrated gel noodles are sucked up into the tubing, whose internal diameter is slightly bigger than that of the noodles (Figure 15a–c). After removal of all traces of the buffer, the tubing is filled with PstI solution (1500 units PstI in 1500 µL of 1× HB), and the tubing looped, with one end connected to the other (Figure 16). The looped, Teflon® tubing-enclosed gels are incubated for 2 h at 37 °C.

4.4.6 Running Second-dimensional Gels

After digestion for 2 h with PstI, the gel noodles are expelled from the tubing into 50-mL Falcon tubes containing 40 mL of 1× TBE buffer. After 10 min of equilibration, the noodles are transferred into the glass slits of the 2nd-D electrophoresis apparatus as shown...
in Figure 17(a) and (b). The space between the agarose
and acrylamide gels is filled with 0.8% SeaKem® agarose
in 1× TBE containing 0.05% BPB. After the overlaid
agarose has solidified, both reservoirs are filled with 1×
TBE and electrophoresis carried out at 150 V for about
24 h, at which time the tracking dye BPB will have reached
the end of the gels.

4.4.7 Autoradiography
The gels are dried and autoradiographed, usually for
3 days, using Kodak X-AR film.

4.4.8 Restriction Landmark Genomic Scanning Profile
A representative result is shown in Figure 18. In this
particular autoradiogram, more than 3000 spots can be
separately distinguished.

4.5 Methods for Spot Cloning

4.5.1 Polymerase Chain Reaction-mediated Method
The principles behind the method are illustrated in
Figure 19(a) and (b). The method consists of PCR
amplification of adapter-ligated spot DNA fragments
without the exclusion of similar-sized co-localized DNA
fragments, following selective ligation with the NorI–dT
vector. It can be expected that the similar-sized DNA
fragments are present in abundance and therefore will
work well as DNA carriers to prevent loss of the target
spot DNA through the cloning step. The method is highly
advantageous when the total DNA sample prepared for
cloning is limited, as only a few micrograms of DNA in all
is sufficient for cloning. This method is applicable to any
spot DNA derived through RLGS using different sets of
restriction enzymes for analysis, simply by changing the
adapters, PCR primers and vectors for the subcloning.
The method is also applicable to RLCS spot cloning.

4.5.1.1 Apparatus and Reagents

E. coli DNA ligase (Takara); 10× ligation buffer for E. coli DNA ligase [300 mM Tris-Cl (pH 8.0), 40 mM MgCl₂, 100 mM
(NH₄)₂SO₄, 12 mM EDTA, 1 mM NAD, 0.05% BSA];
spin column (Chroma Spin-100™; Clontech); NACS™ column (BRL); 10 µM NorI and HinfI adapters (preannealed
double-stranded oligonucleotides; 5’-ACGCCAGGTTTTCCAGTCAAGCGC-3’ and 5’-pGGCCGCGTCGTA
GTGACTGGGAAACCTGCGGT-3’ for NorI site and
5’-pANTCGTGTGACTGACCCAGAATCC-3’ and
5’-GGATTTGCTGGTGCAGTACAG-3’ for HinfI site); forward primer P77 (10 µM; 5’-AGGGTTTCCCAGTCA
ACGACCGG-3’); reverse primer Ad2-2 (10 µM; 5’-pTTGCTGGTGCAGTACAGANTC-3’); Taq DNA
polymerase (Takara); 10× PCR buffer [100 mM Tris-Cl (pH 8.3), 500 mM KCl, 15 mM MgCl₂]; dNTP mixture (2.5 mM each of dATP, dCTP, dGTP and dTTP); 50 ng µL⁻¹ NotI–dT vector (a linearized dephosphorylated plasmid vector with both a NotI terminus and 3’-dT protruding terminus); linearly polymerized acrylamide (1% solution); 10× HB; 500 mM Tris-Cl (pH 7.4); T4 DNA ligase (Takara); 10× buffer for T4 DNA ligase [500 mM Tris-Cl (pH 7.5), 100 mM MgCl₂, 100 mM DTT, 10 mM ATP, 0.1% BSA]; 50% PEG6000.

4.5.1.2 Procedures For the basic operations, such as electroelution, PCI extraction, ethanol precipitation, enzyme treatment and PCR reaction, see the general protocol books.¹⁰ The restriction enzymes NotI, BamHI and HinFI are used in this experiment as RLGS restriction enzymes E₁, E₅ and E₆, respectively. A 1-µg amount of the sample to be cloned is mixed with the same quantity of the end-labeled sample and subjected to the RLGS procedure. Following autoradiography, the target spots are cut out and their DNA fragments electroeluted and extracted with PCI, followed by ethanol precipitation using 10 µg of linearly polymerized acrylamide as a carrier, and then dissolved in 3 µL of TE.

A third of each DNA fragment is ligated overnight at 16 °C with NotI and HinFI adapters.

DNA solution 1 µL
10× buffer for E. coli DNA ligase 0.5 µL
Adapter for NotI 0.5 µL
Adapter for HinFI 0.5 µL
E. coli DNA ligase 1 µL (30 U)
DW 1.5 µL

After incubation, the ligation mixture is diluted to 40 µL and subjected to a spin column, after which the eluate is PCR-amplified through 30 cycles using the primers P77 and Ad2-2 as follows:

DNA solution (adapter-ligated) 37.5 µL
dNTP mix 5 µL
10× PCR buffer 5 µL
P77 primer 1 µL
Ad2-2 primer 1 µL
Tag DNA polymerase 0.5 µL

Figure 17 Schematic view of connection of 1st-D gel noodle to 2nd-D acrylamide gel. After laying the agarose gel noodle in one of the glass grooves, dissolved agarose (kept at 60 °C) is injected between the noodle and the acrylamide gel using a 5-mL syringe. Damage to the acrylamide gel surface by the syringe needle must be avoided.

Figure 18 RLGS profile of rat brain tissue. NotI, PvuII and PstI were used as E₁, E₅ and E₆, respectively.
RESTRICTION LANDMARK GENOMIC AND cDNA SCANNING

Figure 19 Schematic representation of PCR-mediated method of RLGS spot cloning.

The conditions for PCR amplification are 94 °C for 1 min, 60 °C for 1.5 min and 72 °C for 2 min. The PCR products are directly applied to the polyacrylamide gel electrophoresis and stained with ethidium bromide. The amplified bands are cut out and electroeluted, followed by purification through an NACS™ column. After ethanol precipitation, the resultant DNA is suspended in 10 µL of TE.

The amplified DNA is kinated and digested with NotI as follows:

- DNA solution (amplified) 10 µL
- 10× kination buffer 5 µL
- 100 mM ATP 1 µL
- DW 30 µL
- T4 DNA polynucleotide kinase 4 µL

After incubation for 60 min at 37 °C, the DNA is extracted with PCI, precipitated with ethanol and suspended in 5 µL of TE, followed by NotI digestion.

- DNA solution (kinated) 5 µL
- 10× HB 1 µL
- NotI 1 µL (10 U)
- DW 3 µL

Following NotI incubation for 60 min at 37 °C, the DNA is again extracted once with PCI, condensed through ethanol precipitation and suspended in 3.5 µL of TE. The resultant NotI-digested DNA is then ligated with NotI–dT vector:

- DNA solution (NotI-digested) 3.5 µL
- NotI–dT vector 2 µL
- 10× buffer for T4 DNA ligase 1 µL
- T4 DNA ligase 1 µL (350 U/µL)
- 50% PEG6000 1 µL
- DW 1.4 µL

The product is incubated overnight at 16 °C and transformed into the appropriate E. coli, ex HB101.

4.5.1.3 Results We have succeeded in cloning much target spot DNA by the PCR-mediated method. Almost 70% of the target DNA fragments have been successfully cloned. One of the disadvantages of the method is that it proved impossible to clone spot DNA fragments of more than 1000 bp in size. This may have been due to inefficient amplification of the target DNA fragments by PCR reaction. Nonetheless, the method has also been applied to cloning the spots from the RLCS system. Several target DNA fragments (genes) have already been cloned.

4.5.2 Restriction Trapper-mediated Method

The principles behind enrichment of target DNA fragments using a restriction trapper are illustrated in Figure 20. The restriction trapper, the key material for this process, consists of a hairpin-looped oligolinker covalently linked to the surface of latex beads (Figures 21 and 22). The method is based on purification of the target
Figure 20 Procedure for RLGS spot cloning with restriction trapper mediation. The presence of many unlabeled invisible fragments in the target spot of conventional RLGS gels prevents specific cloning. Eluting DNA fragments from the RLGS gel with restriction trapper purifies the DNA, which can then be cloned.

DNA fragments by the restriction trapper through ligation at their restriction landmark sites. Purified target DNA fragments sufficient for cloning can be obtained by increasing the initial amount of genomic DNA. It is therefore necessary to prepare several hundred micrograms of the genomic DNA and the rather specialized restriction trapper. The method is nevertheless useful because (1) the spot DNA fragments are evenly enriched with restriction trapper, independent of fragment size, and (2) DNAs of many spots can be enriched and cloned simultaneously.

4.5.2.1 Apparatus and Reagents

- **HB** [500 mM Tris-Cl (pH 7.4), 100 mM MgCl₂, 1 M NaCl, 10 mM DTT]; 0.1% BSA; 0.1% Triton X-100; 10× low buffer (LB) [100 mM Tris-Cl (pH 7.5), 100 mM MgCl₂, 10 mM DTT]; **NotI** restriction trapper, pre-washed once with TE and adjusted to 5% solution with TE (Gene Trapper R-NotI; Japan Synthetic Rubber); T4 DNA ligase (Takara); 10× buffer for T4 DNA ligase [500 mM Tris-Cl (pH 7.5), 100 mM ATP, 50% PEG6000]; 10× MB [100 mM Tris-Cl (pH 7.5), MgCl₂, 10 mM DTT, 500 mM NaCl]; 3000 Ci mmol⁻¹ [α-32P]dGTP; 6000 Ci mmol⁻¹ [α-32P]dCTP; Sequenase® Version 2.0

4.5.2.2 Procedures

The restriction enzymes NotI, *Pvu*II and *Pst*I are used in this experiment as RLGS restriction enzymes **E₇**, **E₅** and **E₆**, respectively. A 1-mg
amount of genomic DNA is prepared (10 reactions, each of 100 μg) and completely digested with NotI and PvuII.

DNA (NotI-digested) 200 μL
10× HB 20 μL
NotI restriction trapper 20 μL
PvuII (12 U μL⁻¹) 10 μL
DW 170 μL

The NotI-digested DNA is incubated for 2 h at 37 °C and then further digested by PvuII by addition of the following agents:

DNA solution (NotI–PvuII-digested) 50 μL
NotI restriction trapper 20 μL
10× buffer for T4 DNA ligase 15 μL
100 mM ATP 2 μL
50% PEG6000 30 μL
T4 DNA ligase (350 U μL⁻¹) 4 μL
DW 14 μL

The mixture is incubated for 2 h at 18 °C with occasional mixing. After inactivation of the ligase at 65 °C for 15 min, the restriction trapper is recovered by centrifugation at 15 000 g for 5 min followed by washing with TE. The trapper is then treated with PvuII.

DNA (restriction trapper) 45 μL
PvuII (12 U μL⁻¹) 10 μL
DW 395 μL

After incubation for 1 h and washing twice with TE, the trapper is then treated with NotI.

DNA (restriction trapper) 10× HB 10 μL
0.1% BSA 10 μL
0.1% Triton X-100 10 μL
NotI (10 U μL⁻¹) 10 μL

The mixture is incubated for 2 h, at 37 °C, mixing every 30 min. After centrifugation, the target DNA fragments (NotI–PvuII fragments) released from the trapper in supernatant are extracted with PCI, precipitated with ethanol and dissolved in 16 μL of TE. A small portion of the DNA fragments purified by the above method is end-labeled in the presence of [α-32P]dGTP and [α-32P]dCTP with Sequenase® Version 2.0.

DNA (NotI–PvuII fragments) 3 μL
10× MB 1 μL
[α-32P]dGTP 1 μL
[α-32P]dCTP 1 μL
Sequenase® Version 2.0 1 μL
DW 3 μL

The mixture is incubated for 30 min at 37 °C.

The now radiolabeled DNA fragments are mixed with the remaining unlabeled DNA fragments and the whole is subjected to RLGS. After autoradiography, the DNA fragments in the target spots are recovered by electroelution, ligated with NotI–PstI-cleaved plasmid vector and transformed into appropriate E. coli by the conventional method.

4.5.2.3 Results Using this restriction trapper-mediated method, several target DNA fragments have been successfully cloned from RLGS gel spots. 

5 APPLICATION OF RESTRICTION LANDMARK GENOMIC SCANNING

5.1 Potential Applications

RLGS, utilizing the concept of restriction landmarks, has various potential applications in biological research. In general, two major categories of application can be listed, the first being scanning of copy numbers of restriction landmarks across an entire genome. Based on genetic polymorphism or sequence variations between individuals at the restriction landmarks, the entire genome map can be rapidly constructed by high-throughput RLGS Version 1.8. Furthermore, since RLGS needs no DNA probes or STS primers for detecting polymorphisms, a genetic map of any organism, e.g. the Syrian hamster, can be determined. These genetic maps facilitate the analysis of positional cloning of genes responsible for genetic diseases.

The second category of application is scanning of genome-wide methylation conditions, so as to survey both endogenously imprinted genes and potentially expressed genes, based on the correlation of methylation with gene expression. This method of scanning for methylation is named ‘RLGS for methylation’ (RLGS-M). RLGS-M is very powerful, because more than 2000 loci can be surveyed for their methylation status in a
single procedure. Using this approach, our group has already found and reported some imprinted genes in mice.\(^{21,28,29}\) By way of illustration, in the next section we describe the application of RLGS-M to the scanning of methylation status associated with liver cancer in mice.

5.2 Application of Restriction Landmark Genomic Scanning to Cancer Research

5.2.1 Scanning Methylation State with Restriction Landmark Genomic Scanning Using Methylation-sensitive Endonuclease

Restriction landmark sites across an entire genome can be visualized and screened using RLGS techniques. If methylation-sensitive endonucleases are used for landmark cleavage, the appearance of RLGS spots varies depending on the methylation status of the landmark sites. When a landmark site is methylated and thus resistant to digestion, the corresponding RLGS spot disappears. Hence the RLGS technique is applicable to the scanning of the methylation state of landmark sites. We have named this approach ‘RLGS for methylation’ (RLGS-M) and have used it to screen for methylated loci genes\(^{28,30}\) which could contribute to tumorigenesis.

In RLGS-M analysis, the intensity of a spot reflects the copy number of a corresponding landmark site, because the number of end-labeled molecules at landmark cleavage sites corresponds to the level of incorporated radioactivity (Figure 23). Uniform levels of spot intensity are observed in diploid tissues; this is consistent with the cleavage and end-labeling of both alleles for most landmark sites. However, when methylation-sensitive enzymes are used to identify the landmark cleavage sites, the spots are reduced to half- or zero-intensity, respectively, when one or both of the alleles are methylated (Figure 23). GC-rich enzymes such as NotI (GCGGCCGC) or BssHII (GCGCGC) cleave sequences that tend to be located on CpG islands.\(^{31}\) It has been estimated that approximately 89% of NotI sites and 74% of BssHII sites are on CpG islands. Hence the methylation status of CpG islands\(^{13,32}\) can be evaluated using NotI or BssHII to identify landmarks. Moreover, since methylation has been correlated with gene expression, it has been possible to screen NotI and BssHII sites for allele-specific patterns of methylation.

5.2.2 Overview of Cancer

Tumorigenesis is a multi-step process involving both epigenetic and genetic alterations.\(^{31,33}\) The identification of genetic mutations, which cause either increased functioning of proto-oncogenes or loss of functions of tumor suppressor genes, provided a rationale for understanding tumorigenesis. However, the mutation of a single proto-oncogene or tumor suppressor gene is usually not sufficient in itself to cause neoplastic growth, tumor progression depending on secondary events. The genetic targets for these secondary events could be expected to depend on the initiating event and also developmental and tissue-specific factors regulating cell proliferation which arise during cell proliferation. Additional ‘steps’ involving angiogenesis, invasive growth and metastasis generate more serious life-threatening disease. Although the ‘cast of characters’ involved in these processes is large and growing, our understanding of them is complicated by the large number of genes involved, developmental and tissue-specific differences in growth regulation and the stochastic nature of the process.

Alterations in DNA methylation are consistently found associated with tumorigenesis and may play a variety of roles in tumor progression.\(^{35,36}\) In general, tumor DNA is hypomethylated, while hypomethylation is associated with increased gene expression. Several proto-oncogenes have been shown to be hypomethylated in tumors.\(^{35,37}\) By contrast, regional hypermethylation may promote tumorigenesis by silencing expression of tumor suppressor genes, the genes necessary for differentiation and cessation of growth, or hormone receptors which have a role in the growth or properties of the tumor.\(^{38,39}\) In addition, increased
methylation may be mutagenic since 5'-methylcytosine can deaminate spontaneously to T, resulting in a C to T transition.\(^{(35,36)}\) Results indicating that expression of an exogenous DNA methyltransferase can induce transformation of NIH/3T3 cells supports the contention that DNA hypermethylation plays an important role in tumor progression.\(^{(42)}\)

In recent years, a number of new technologies have been developed which can be used for rapidly screening tumors for genetic alteration on a genome-wide basis. Most of these methods depend on nucleic acid hybridization to detect gain or loss of DNA sequences. These methods include comparative genomic hybridization,\(^{(43)}\) representational difference analysis,\(^{(44)}\) PCR analysis of simple sequence length polymorphisms (SSLP)\(^{(45)}\) and RLGS.\(^{(5)}\) Although each method has its advantages and disadvantages, the RLGS method is potentially powerful in terms of the number of loci that it is capable of screening simultaneously, its facilitation of direct cloning of genetic regions which are altered during tumorigenesis\(^{(20)}\) and its ability to detect and localize regional hypermethylation or hypomethylation changes.

---

**Figure 24** RLGS-M profile of normal BSF1 liver DNA produced by the enzyme combination NotI, PvuII and PstI. (a) Fourteen spots showing loss (methylation) in more than 75\% of 30 hepatoma samples are indicated by arrows. (b) A magnified section of the normal RLGS DNA profile containing spot S238 – indicated by the arrow – (1) is compared with the same part from a profile of tumor DNA (2). [Reproduced from Akama et al.\(^{(30)}\) by permission of the American Association for Cancer Research, Inc.]
5.2.3 Analysis of Mouse Liver Tumors for Alterations in DNA Methylation Status Using Restriction Landmark Genomic Scanning Using Methylation-sensitive Endonuclease

The principles by which RLGS-M analysis is used to detect DNA methylation status is shown in Figure 23 through a schematic representation of the RLGS patterns of normal tissues from parents and F1 progeny, as well as of F1 tumor tissue. Polymorphic paternal- (S) and maternal- (B) specific genes are transmitted to F1 progeny by Mendelian inheritance, and show up under general RLGS analysis as half-intensity spots. Using a methylation-sensitive enzyme, such as NotI, we can detect alterations of the DNA methylation status at such sites throughout the genome. When comparing tumor DNA relative to control DNA, methylation of a NotI site in the tumor DNA results in spot loss, whereas demethylation of a NotI site results in the appearance of a new spot. An example of the disappearance of the spot due to methylation in a tumor is illustrated (see Figures 23 and 24b). In order to help characterize the alterations of methylation status in tumor DNA, we utilized interspecific F1 hybrid, strain-specific haploid spots whose chromosomal locations are known through genetic analysis.\(^{(24)}\) The 575 loci/spots (340B- and 235 S-specific) were mapped by RLGS analysis (using NotI, PvuII and PsII) of BSS backcross progeny.\(^{(24)}\) Using the new RLGS Version 1.8,\(^{(7,46)}\) 507 of the mapped spots provided useful information for the rapid analysis and localization of genomic alterations such as changes in methylation at landmark sites.

RLGS-M analysis was performed on 30 liver tumor DNA samples from 14 interspecific F1 hybrid mice offspring of S and a transgenic B57BL/6 (B6) line containing the SV40 T antigen early region connected to a mouse major urinary protein (MUP) enhancer/promoter.\(^{(30)}\) In cancer tissues, changes in the intensity of the RLGS spots may reflect DNA loss, rearrangement or amplification, and also alterations in methylation as described above. Random alterations would be expected to occur due to genomic instability in the course of tumorigenesis, but some alterations may be primary aberrations that promote tumorigenesis. These primary genomic aberrations would be expected to occur at a high frequency in particular tumor types. We believe that altered loci detected in 22 of the 30 tumor samples (75%) may be significantly associated with tumorigenesis. In all, 24 spots were detected which showed a loss or reduction in intensity in 75% of the tumor DNA samples (see Table 2). The loss of these spots could have resulted from either of two primary causes: loss of heterozygosity (LOH) (i.e. DNA loss) or methylation of the landmark NotI site. To distinguish between these two possibilities, we combined the information on spot intensity with that on chromosomal location. We assumed that chromosomal regions which displayed more than two contiguous loci/spot losses were likely to reflect the deletion of DNA as we had found previously,\(^{(20)}\) whereas solitary loci/spot losses probably reflected methylation at the landmark sites. Confirmation of this assumption required the cloning of the spots and analysis of tumor-specific alterations by means of Southern blotting, using the spot clones as probes. By this means, we determined that loss or reduction in intensity of 14 solitary spots resulted from landmark methylation and, furthermore, that this methylation occurred in more than 75% of the tumor samples. These 14 spots are shown with their spot identification numbers in Figure 24(a).

* Approximately 20 tumors were analyzed for each spot. [Reproduced from Akama et al.\(^{(30)}\) by permission of the American Association for Cancer Research, Inc.]

Part of the RLGS gel containing a representative spot, S238, is shown (indicated by the arrow) under magnification in Figure 24(b). The intensity of S238 is clearly reduced in tumor tissue. Characterizations of the 14 spots which displayed such reduced intensity are presented in Table 3. Locus number is designated as D#Rik- or D#Ncvs-. Each of the 14 spots were classified as solitary losses. Although four of the loci, D5Rik119, D5Ncvs4, D5Rik122 and D5Rik124, are located on chromosome 5, losses at these loci are all solitary. The localization of these four spots, however, is restricted to the centromeric half of the chromosome, indicating that a high frequency of methylation sites associated with tumorigenesis may be localized in this area.

5.2.4 Isolation of Spot Clones and DNA Sequence Analyses

In order to characterize further the nature of the genomic alterations associated with spot loss at the loci in question, and potentially to identify a gene at a given locus, we cloned 13 of the 14 spots using the restriction trapper-based RLGS spot-cloning method described in section 3.4.2.\(^{(30)}\) DNA sequence analysis and a homology search against existing DNA databases revealed that two
of the cloned spots, S130 and S238, were identical with mouse mac25 and the mouse tumor suppressor gene p16/CDKN2, respectively.

5.2.5 Southern Blot Analysis Using Spot Clone S238 as a Probe

To examine the methylation status of p16/CDKN2 in tumor tissues, Southern blot analysis was performed using the cloned spot (S238) as a probe. Representative results are shown in Figure 25. The S238 probe used for hybridization is identical with the distal half of the first exon of p16/CDKN2. The S238 probe detects a PvuII polymorphism between B6 and S in normal liver DNA (Figure 25, lanes 1 and 2). When these PvuII fragments are digested with NorI, the S allele alone is cleaved into a 3.9-kb band (lanes 1 and 3). Thus, the NorI site from the spot clone S238 (NorI–PstI fragment) is present in the S allele but absent from the B6 allele. Lanes 5–12 are DNA from tumor samples digested with both NorI and PvuII. In tumor XX-2 and K3-1 (lanes 5 and 6), the NorI–PvuII 3.9-kb S allele is of reduced intensity whereas the 6.0-kb PvuII–PvuII S band is of increased intensity, indicating that the NorI site of the S allele has become methylated. Tumors L3-3, F3-1B and F3-5 show both methylated and unmethylated S bands of almost the same intensity (lanes 7, 9 and 10), suggesting that 50% of the S allele of the p16/CDKN2 gene has been methylated. Tumors B3-1 and N3-2C have no methylated 6.0-kb S band (lanes 8 and 12) but the intensity of the unmethylated 3.9-kb band is reduced, implying that the S allele of the p16/CDKN2 gene has been partially lost in this tumor sample. In tumor G3-2, both the methylated and unmethylated S bands are of reduced intensity and the B6 band is completely absent (lane 11), indicating that the S allele of the p16/CDKN2 gene is partially methylated and the B6 allele deleted.

5.2.6 Methylation of p16/CDKN2 and Tumorigenesis

Spot clone S238 was found to contain sequences identical to exon 1 of the p16/CDKN2 (INK4a, MTS1) gene. Homozygous and heterozygous deletion and also point mutations of this gene on 9p21 are commonly observed in human cancers. Several reports also indicate that methylation of a 5’ CpG island which includes exon 1 is associated with transcriptional silencing of p16 in human tumors. The product of the p16/CDKN2 gene, p16, binds to CDK4 and CDK6, preventing their interaction with cyclin D and subsequent cell cycle progression. The CDKN2 gene also encodes an unrelated protein, p19, which arises from an alternative reading frame. This protein (p19) is also capable of inducing arrested growth although the mechanism is not understood.

Southern blot analysis of DNAs from liver tumors, using the S238 spot clone, indicated that the S NorI site within exon I was completely or almost completely methylated in 19 of 24 samples. Five samples showed partial methylation (Figure 25, lanes 8 and 12) or a combination of partial methylation and partial gene loss (lane 11). It is not known whether the tumors are heterogenous with respect to alterations at this locus. This region (exon 1) corresponds to the same region of the p16/CDKN2 gene which is hypermethylated in human tumors and results in transcriptional silencing. Currently, it is not clear whether methylation silences p16 expression in the liver tumors analyzed in this study.

Since the liver tumors studied were induced as a result of SV40 T antigen expression, the Rb gene is presumably ‘inactive’. P16 is considered to be upstream of pRb since it normally forms complexes with CDK4 and/or CDK6, inhibiting their interaction with cyclin D.

and the subsequent phosphorylation of pRb necessary for cell cycle progression from G1 to S.\(^{(56)}\) Hence it is difficult to perceive what the consequence of loss of p16 expression would be in an Rb-negative cell. Indeed, ectopic expression of p16 in Rb-negative cells does not result in G1 arrest.\(^{(56)}\) Recent experiments indicate that p16 mRNA levels are normally elevated in Rb-negative cells or in SV40 T antigen-transformed cells, suggesting that Rb is normally a transcriptional repressor of p16.\(^{(57)}\)

What, then, is the significance of p16 methylation and its presumed transcriptional silencing in the SV40 T antigen-induced liver tumors? Clearly, more work is necessary to elucidate the consequences of p16 methylation in this system. Recent studies indicate that D-type cyclins interact with a novel myb-like transcription factor, DMP1.\(^{(58)}\) This suggests that cyclin D-dependent kinases may regulate gene expression through a mechanism independent of Rb. This pathway may function to link regulation of some genes with the cell cycle but may still be susceptible to regulation via p16–CDK4/CDK6 interaction. The methylation of p16 in the SV40 T antigen-induced liver tumors may perturb this pathway.

We conclude that RLGS-M can be used for a genome-wide search for tumor-related alterations in the DNA methylation status. RLGS-M can detect alterations in known tumor suppressor genes and provides a means for detecting and cloning novel genomic regions which have alterations in methylation status related to tumor progression.

1 INTRODUCTION

Ribonucleic acids are negatively charged polymers assembled from four different types of monomers. Each monomer is made of an invariant phosphorylated sugar to which is attached one of the four standard nucleic acid bases; the pyrimidines uracil and cytosine, and the purines guanine and adenine. The first level of organization is thus the sequence of bases attached to the sugar–phosphate backbone. In salty water, the RNA molecules fold back on themselves via Watson–Crick base pairing between the bases (A with U, G with C or U) leading to double-stranded helices interrupted by single-stranded regions in internal loops or hairpin loops. The enumeration of the base-paired regions or helices constitutes a description of the second level of organization, the secondary structure. The methods available to deduce the secondary structure of an RNA molecule are mainly of three types: the phylogenetic approach, the theoretical prediction, and chemical/enzymatic methods. The secondary structure of an RNA molecule is experimentally accessible and its content measurable. Under appropriate conditions, structured RNA molecules undergo a transition to a 3D fold in which the helices and the unpaired regions are precisely organized in space. This folding process usually depends on the presence of divalent ions like magnesium ions and on the temperature. The tertiary structure is the level of organization relevant for biological function of structured RNA molecules. Sections 2–4 discuss these structural properties of RNA.

The instrumental methods leading to the elucidation of the tertiary structure are then described. The first method relies on X-ray crystallography of single crystals of purified RNA molecules. The second most important structural method is nuclear magnetic resonance (NMR). Finally, the phylogenetic method coupled to computer modeling and experimental approaches is described. An overview of the RNA motifs underlying the assembly of RNA molecules in complex tertiary folds is given. These include loop–loop interactions, some of which constitute pseudoknots, tetraloops and their receptors, as well as structured internal loops such as the 5S loop E motif. The roles of non-Watson–Crick base pairing for tertiary structure is emphasized throughout.

2 CHEMICAL STRUCTURE OF RNA

Nucleic acid biopolymers comprise the DNA and RNA molecules. These two types of molecules possess very different functional roles. In brief, DNA molecules (deoxyribonucleic acids) contain the genetic code, whereas the more versatile RNA molecules (ribonucleic acids) are
Figure 1 Chemical structure of a -AUGC- RNA sequence drawn from the 5' to the 3' end. The RNA bases are frequently modified, especially in transfer RNAs (tRNAs), where thymine (5-methyl U or T) or pseudouridine (Ψ, in which there is a C-C glycosyl bond between the base C5 and the sugar C1' atoms) are often found.

Figure 2 Possible interaction sites around the standard Watson-Crick base pairs G-C and A-U as well as the wobble G-U pair and the sugar-phosphate backbone atoms. The edges facing the deep and shallow grooves of RNA helices are indicated. Hydrogen bond acceptor sites are marked by ‘inward-pointing bold’ arrows, hydrogen bond donor sites are marked by ‘outward-pointing bold’ arrows, weak hydrogen bond donor sites (C-H groups) are marked by thin arrows. The RNA 2'-hydroxyl group (see inset) displays simultaneously an hydrogen bond donor and acceptor potential.
involved in almost all crucial life processes and especially in the translation of the genetic code into proteins.

The four ribonucleosides that incorporate the purine bases, adenine (A) and guanine (G), and the pyrimidine bases, uracil (U) and cytosine (C) constitute the basic building blocks of a RNA polymeric chain (Figure 1). These nucleosides comprise a ribose sugar ring and a purine (A, G) or a pyrimidine (C, U) base. They are connected together by a phosphodiester linkage. The nucleoside and its phosphodiester unit is called a nucleotide. The bases of an RNA polymeric chain associate with the complementary bases of the same chain or of another RNA chain by forming purine–pyrimidine A–U or G–C Watson–Crick base pairs (see Figure 2). The association of two self-complementary strands results in the formation of a right-handed double helical structure (Figure 3).

Although DNA and RNA molecules possess very distinct biological functions, chemically RNA differs from DNA only in two aspects: (a) the absence of a methyl group at position 5 of the uridine (U), and (b) the distinct biological functions, chemically RNA differs of a right-handed double helical structure (Figure 3).

In contrast to DNA but similar to proteins, single-stranded polynucleotide RNA chains can fold in a variety of complex 3D structures. This ability to form complex folds is exemplified by tRNA molecules which are constituted by a single chain of about 70 nucleotides (Figure 2). The analogy with proteins includes also the fact that some RNA molecules, called ribozymes, are able to perform biologically crucial catalytic reactions.

In nucleic acids, there are six torsion angles in the sugar–phosphate backbone with an additional one between the base and the sugar (see Figure 5 in Berman’s article X-ray Structures of Nucleic Acids). Sundaralingam reduced severely the variations in two torsion angles and constrained the other five to preferred domains of variations. Thus, the torsion angles about the C–O bonds remain at about 180°, whereas the sugar rings adopt either the C3′-endo or the C2′-endo puckers and the base is either in an anti or a syn orientation with respect to the sugar. In proteins, the torsion angles on either side of the peptide bond constitute the main flexible links, whereas in nucleic acids the phosphodiester bonds themselves direct chain re-orientations.

The RNA molecules, in helical form (Figure 3), are not much affected by changes in their environment and adopt essentially the A-form in the helical parts of their structures under nearly all conditions. However, many RNA molecules need specific divalent cations in order to fold properly into biologically active conformations.

![Figure 3](image-url)
The absence of such ions may induce profound structural changes, such as loss of 3D interactions.\(^7\)

Non-Watson–Crick base associations\(^8\) are often found in RNA structures where they serve as specific recognition elements for proteins, nucleic acids, and ligands, or as ion-binding sites. Such noncanonical base pairs are linked by at least one interbase hydrogen bond and occasionally involve water-mediated base–base interactions. Wobble base pairs are typical of RNA molecules and can be inserted without great distortions into regular Watson–Crick helices.\(^9\) The wobble base pairs display a characteristic shift of their Watson–Crick interaction sites. Two of these sites point, respectively, toward the shallow and deep grooves and are, thus, completely accessible to the solvent. Wobble base pairs comprise essentially the G\(\rightarrow\)U base pairs. For these base pairs, the guanine amino group protrudes into the shallow groove and the O4 atom of the uracil

**Figure 4** Representation of the secondary and tertiary structure of an artificial group I intron based on that of Tetrahymena thermophyla. Some tertiary motifs are highlighted. Motifs I and II are loop–loop interactions leading to a helical structure maintained via standard Watson–Crick pairings. Motif III is constituted of a GUGA tetraloop interacting with the shallow groove of two base pairs embedded within a helix. Motif IV is made of a GAAA tetraloop interacting with its receptor, the 11nt-motif, a complex structure maintained by an AA-platform (two consecutive As in the same plane\(^{26}\)) and an A\(\rightarrow\)U Hoogsteen base pair. In motif V, part of an A-rich bulge interacts with C–G pairs in the shallow groove of a helix.
base point towards the deep groove. Furthermore, G•U base pairs display a deep groove side that is lined with three hydrophilic acceptor atoms (N7, O6, O4) and no hydrophilic donor atoms, whereas the shallow groove side presents a cavity wide enough for trapping a water molecule. Both grooves present, therefore, very unique recognition patterns.\(^{(10)}\)

### 3 Definitions of Secondary and Tertiary Structures

Probably the most straightforward definition of secondary structure would include any nucleotide such that both itself and one at least of its immediate neighbors in the 5′ or 3′ direction are involved in classical (Watson–Crick and G•U) base pairing with a stretch of nucleotides in antiparallel orientation (Figures 3 and 4). Ideally, one would like an RNA secondary structure to be a planar graph which can be represented as a tree, i.e. the lines connecting the paired bases do not intersect.\(^{(11)}\) The secondary structure will define various elements. A hairpin loop is formed when an RNA strand folds back on itself. In an internal loop, at least one base is unpaired on each strand of the loop separating two paired regions. A mismatch is a special type of internal loop for which only one nucleotide is unpaired on each strand. A bulge has unpaired nucleotides on only one strand. The other strand has uninterrupted base pairing. A multibranched loop occurs when double-stranded regions separated by any number of unpaired nucleotides, come together.

In the next level of organization, the tertiary structure, the secondary structure elements are associated through numerous van der Waals contacts, specific hydrogen bonds via the formation of a small number of additional Watson–Crick pairs and/or unusual pairs involving hairpin loops or internal bulges. The parsing of energy levels between secondary and tertiary structures is reasonable in large RNAs, considering the relative energies and the clear identification of the secondary structure elements. In some cases, it is even possible to cut RNA molecules into modular domains which can re-associate only through tertiary contacts.

### 4 RNA Tertiary Motifs

RNA tertiary structure comprises those interactions involving (a) two helices, (b) two unpaired regions, or (c) one unpaired region and a double-stranded helix. The interactions between two helices are basically of two types: either two helices with a contiguous strand stack on each other, or two distant helices position themselves so that their shallow grooves fit. An unpaired region belongs to either a single-stranded stretch (forming an internal loop or a bulge) or a hairpin loop closing a helix. Interactions between two unpaired regions lead to pseudoknots if a single loop is involved and to loop–loop motifs otherwise (Figure 5). Interactions between an unpaired region and a double-stranded helix can lead to various types of motifs. Pairing of a single-stranded stretch, either in the deep or the narrow groove of a double helix, yields a triple helix. One motif is known where the unpaired region constitutes a terminal loop, in which -GNRA- tetraloops bind the shallow groove of the helix (see Figure 6). Those motifs involving single-stranded stretches are especially rich in potential to form tertiary structure because they can lead to co-axiality between helices. Depending on their sequence, internal loops or bulges could constitute 3D motifs, but such motifs have not yet been characterized. The co-axial stacking of helices, together with specific helix–helix contacts or helix–loop interactions, lead to compact RNA assemblies, generally in the presence of divalent ions or polyamines (Figure 7).

### 5 Instrumental Methods

The experimental observations used for deriving a 3D structure, and thus the tertiary motifs, can be of quite different nature depending on the techniques employed.
Figure 6 The three main tertiary motifs mediated by the tetraloops of the GNRA family. In the first two (a) and (b), the third and fourth residues of the GYRA loop forms triples in the shallow grooves of helices so that G binds a U•A pair and A a C–G pair. In the third type of contact (c), a GAAA tetraloop binds a complex 11nt-motif with a central U•A in the Hoogsteen configuration. Each A of the loop binds principally a different base pair in the receptor.

Figure 7 Stereoview of the modeled architecture of the intron of Tetrahymena thermophyla. Some of the tertiary motifs, shown in black, are numbered as in Figure 4.

These range from biophysical methods (X-ray diffraction data, NMR couplings or nuclear Overhauser effects, and other spectroscopic methods such as ultraviolet, Raman, or circular dichroism), to biochemical approaches (chemical probing or enzymatic attack), and biological data (sequences, phylogenies, and in vitro selection). High-resolution X-ray crystallographic analysis (diffraction data at 1.5–0.9 Å resolution) yields a wealth of unequalled 3D information. Nucleic acids are difficult to crystallize because they are highly charged macromolecules which, in case of RNA molecules, can undergo spontaneous cleavages. In addition, large, nucleic acids and especially RNAs, often exchange between various base pairings and foldings.

Recently, several new RNA crystal structures have appeared, extending our structural knowledge enormously since the days of the tRNAs. These developments were possible first following the introduction of methods for preparing RNA molecules on a large scale with either chemical synthesis or using the T7 DNA-dependent RNA polymerase and, second, following progress in crystallographic techniques especially cryocrystallography and the availability of synchrotron sources (see the article X-ray Structures of Nucleic Acids). NMR has proved useful in this area (reviewed in the chapter by Eriksson Nuclear Magnetic Resonance and Nucleic Acid Structures). Chemical and enzymatic probing of nucleic acids in solution yields important information on the stability of the structures and on those bases protected from chemical or enzymatic attack. However, such experimental approaches do not reveal the nature of the interacting partners. Cross-linking experiments have the potential to give that information, but the cross-linking reactions take place in an assembly of molecules generally not all in the same state, and it is difficult to prove that the reactions occurred solely on functional molecules. Sequence data are extremely rich in potential 3D information, as they result from adaptive evolution over millions of years. Thus, if the function is identical and the sequences are sufficiently diverse, the noise level (or covariations resulting from contingencies) will be decreased by sequence comparisons.

5.1 Physical Methods

The physical methods used for determining RNA tertiary structure are described in other articles. The most accurate method relies on X-ray diffraction of single crystals (Figure 8), as reviewed in the article X-ray Structures of Nucleic Acids. The development of NMR spectroscopy has progressed and allowed the determination of several solution structures of free RNAs as well as of RNAs complexes with peptides, proteins or antibiotics. This approach is reviewed in the chapter by Eriksson Nuclear Magnetic Resonance and Nucleic Acid Structures. Most published structures are accessible and can be retrieved from the nucleic acid database (http://ndbserver.rutgers.edu/). The RNA tertiary structure is subtended by the secondary structure and this
needs to be established before large-scale synthesis is envisaged for crystallogenesis or NMR experiments. The best way to derive secondary structures is by using sequence comparisons.

5.2 Phylogenetic Approach

When a set of homologous sequences (homologous sequences have common ancestry and function) is available, one can search, with the help of a rough alignment, for compensatory base changes that maintain base-paired helices and, therefore, derive the secondary structure. When only one sequence is available or when RNAs are not conserved among a sufficiently diverse set of organisms, theoretical models of predictions, have to be associated with experiments. The related knowledge is based on a set of constraints, the thermodynamic model, and the available experimental data on the molecule.

Comparative analysis of nucleic acid sequences has been widely used for the detection and evaluation of similarities and evolutionary relationships. With RNA molecules, sequence alignments and RNA 2D prediction are intimately related. Comparative analysis is based on the biological paradigm that macromolecules are the product of their historical evolution and that functionally homologous sequences will adopt similar structures.

The sequences are first aligned and then searched for compensatory base pair changes. If, during evolution, a base has been modified in a strand of a potential helix (mutation), then this modification must have been compensated on the complementary strand in order to maintain the structure. The presence of several compensatory changes (two or more) in a potential helix allows one to assert the existence of the helix in the structure. Several secondary structure models have been generated by using comparative analysis: tRNA,[13] 16S rRNA,[14] or group I and group II self-splicing introns.[15] The method requires that the molecules compared are sufficiently different to provide numerous instances of sequence variations with which to test pairing possibilities but that the molecules do not differ so much that homologous residues cannot be aligned with confidence.[16]

In an alignment, the objective is to juxtapose related sequences so that homologous residues in each sequence occupy the same column in the alignment. Standard alignment programs dedicated to molecular biology can be used for that purpose. More recent programs, dedicated to the alignment of RNA sequences, allow the user to manipulate interactively the proposed alignment (such as DCSE,[17] ALIGNOS[18]). They offer functions

---

**Figure 8** The cumulative number of RNA crystal structures alone (light shading) and in complexes (in dark) accessible in the nucleic acid database (http://ndbserver.rutgers.edu/).
dedicated to secondary structures as well as an interactive environment for manipulating the alignment.

Other recent and interesting programs automatically reconsider the alignment by taking into account new sequences and the pre-existing knowledge of the secondary structure.\(^\text{(19)}\) Indeed, with the growing number of sequences, specific RNA databases are created and new sequences have to be added quickly in structured databases of homologous RNA molecules. In such databases, it is very desirable that sequences are aligned in accordance with the preservation of secondary structural features. Because, in an alignment, optimal structural elements can be misaligned, the program RNAAlign\(^\text{(19)}\) makes it possible to align a group of aligned sequences with a new sequence, using positions of high sequence conservation as a guide and a common secondary structure of the group as a guide for determining the secondary structure of the new sequence. Thus, RNAAlign does not suppose that the related sequences are correctly aligned but instead reconsiders the alignment.

5.3 Computer Modeling

Molecular modeling attempts to assemble the 3D structure of a macromolecule on the basis of a mixture of theoretical and experimental data. Hence, prediction methods range from mathematically oriented approaches, relying solely on computer algorithms, to pragmatic and operational approaches in which insight comes from both theory and experiment. Modeling can be viewed as a heuristic tool which should help in the rationalization of experimental observations but also should suggest new relationships between the various components of the modeled molecule. Modeling relies on an existing body of knowledge and, therefore, necessitates an integration of that accumulated knowledge in a form which can be exploited. Hence, the importance of organized and annotated data banks.

The power of visualizing spatial relations is such that models need not be always detailed. In the end, the validity and the accuracy of the model obtained will depend on the nature of the experimental observations collected. However, a mathematical proof guaranteeing the correctness of the derived model is only possible with crystallographic methods (the Fourier theorem). Otherwise, the best that can be achieved is a network of intermolecular crystal packing contacts.\(^\text{(23)}\) Similarly, the recognition motif between the GAAA tetraloop and its 11nt-receptor was identified by in vitro experiments using selection methods\(^\text{(24)}\) before being observed by crystallography.\(^\text{(25,26)}\)

6 CONCLUSIONS

RNA molecules are often restricted to their roles as intermediate between the genomic DNA and the active proteins. This view has changed following the discovery of catalytic RNA by S. Altman and T. Cech:\(^\text{(27,28)}\) RNA is nowadays the only molecule with the two properties of being a depository of genomic information with catalytic potential. Chemical catalysis requires a precise positioning of atoms in space and, therefore, RNA must achieve complex tertiary folds in order to reach transition states. Because RNA molecules carry one negative charge per residue, the compact assembly of large RNAs presents a formidable physical problem. The architecture of large structured RNAs is dominated by helix formation and co-axial stacking of helical stems with loop–loop interactions and GNRA/motifs prevalent as domain anchors.\(^\text{(29)}\) Although the recurrent tertiary motifs can be identified by sequence analysis coupled with chemical probing and 3D modeling, the precise and subtle atomic details require X-ray crystallography or NMR techniques in order to be unveiled.

The developments in chemical and molecular biology techniques have allowed the circumvention of some of the difficulties in the crystallization of RNA molecules and one can hope to see a continuous progression in the number of crystal structures of RNA molecules. Similarly, NMR spectroscopy has become a decisive tool for the unravelling of RNA motifs and complexes between RNA fragments and other ligands, such as antibiotics. Not every single RNA molecule is as highly structured as a self-splicing group I intron. However, it is common to find structured regions in functionally important domains of eukaryotic messenger RNAs, such as the 5′- or 3′-untranslated regions, in eubacterial promoters or
Shine–Dalgarno regions, and naturally in control regions of viral genomes. In addition, new structured RNAs are still being discovered, like the tmRNAs or the RNA part of the ribonucleic particle telomerase. Structured RNAs are often part of complexes with proteins, sometimes a single one as in RNaseP, or with 21 different proteins such as 16S rRNA in the 30S eubacterial ribosomal particle.

Sequencing by hybridization (SBH) determines the sequences of DNA or RNA targets using hybridization data obtained from sets of overlapping oligonucleotide probes of known sequence. SBH shares interesting parallels with computer-based keyword searches of text files. In SBH, chemically synthesized short oligonucleotides (usually 4–25 bases in length) are hybridized to the target under conditions that predominantly allow formation of fully complementary probe/target hybrids. An oligonucleotide hybridization search is effectively a highly parallel molecular computation process with fully random access to the polynucleotide chain “input data”. The target sequence is assembled by aligning sequences of the subset of positively hybridizing oligonucleotides. Probe sequence overlap allows indirect assignment of which of four bases corresponds to each position in the analyzed DNA chain, without performing any actual positional measurements on the sample. The fundamental characteristics of the SBH process confer unique opportunities for miniaturization and parallel analyses (currently in the form of high-density arrays), leading to rapid, cost-effective DNA sequencing. A unique advantage of SBH is its ability to analyze in a single reaction complex DNA or RNA samples that may be thousands of bases long. Hybridization of smaller selected subsets of probes provides a very efficient way of partially sequencing and fingerprinting samples. A very important advantage of SBH is that in a single reaction each base is “read” by multiple overlapping probes. To achieve these advantages, hybridization reactions are miniaturized and coupled with automated data acquisition and efficient computational analyses that can process data sets containing both false-positive and false-negative probe scores. Successful assembly of long target sequences involves synthesis and hybridization of a large number of long probes, due to the higher probability that given short oligonucleotide sequences will be repeated within the target sequence. Overall, SBH is a rapid and cost-effective method of obtaining large amounts of accurate DNA sequence information.

1 INTRODUCTION

Living organisms are self-encoded systems that possess a precise set of instructions, recorded in the sequence
of their DNA or RNA, that uniquely specifies the organism’s development and function. The nucleotide sequence of a DNA or RNA molecule is the specific order of nucleic acid bases in a polynucleotide chain that may be tens of millions of bases long. There are four bases commonly present in DNA: adenine, cytosine, guanine, and thymine (A, C, G, and T respectively). In its natural state, DNA is a double helical molecule, in which two complementary single-stranded DNA chains specifically intertwine with one another. Each purine DNA base in one chain recognizes and binds a specific pyrimidine partner in the other, A to T, and G to C. In this way, the sequence of each strand specifically and unambiguously defines the sequence of its complementary partner, which is of critical importance in the process of DNA replication and cell division.

The ability to efficiently read the sequences of genomic DNA or RNA molecules is essential to understanding and diagnosing genetic diseases, developing new medical treatments, engineering new traits in plants and animals, and unraveling developmental and evolutionary pathways of living organisms. Since the discovery of DNA’s helical structure by Watson and Crick in the 1950s there have been intense efforts to develop biochemical, chemical, and physical methods to sequence individual genes or whole genomes. The efforts have culminated in the Human Genome Project, an international research project initiated in 1986, whose goal is to completely sequence the 3 billion nucleotides of the human genome.

The Human Genome Project, while of enormous importance, does not represent a complete answer to the many critical questions posed by human genetics. The maximum benefit of sequence information is obtained in comparative genome studies between various species and in correlation studies that relate individual sequence and phenotype differences. Such studies require sequencing the genomes of thousands of individuals and species. This situation has fueled a demand for dramatically more efficient ways of sequencing or fingerprinting DNA.

There are three principal ways to obtain partial or complete sequence information for a DNA fragment: (1) sequence-specific DNA degradation, synthesis, and/or separation; (2) sequence-specific DNA hybridization (strand pairing); and (3) nucleotide chain visualization. The first two approaches are currently used in many applications. Nucleotide chain visualization methods are still in the initial phases of development.

Within the first category of sequencing techniques, the automated Sanger gel electrophoresis method is currently most frequently used. This technique involves randomly terminating the synthesis of an unknown DNA at specific bases, followed by exact size (length) determination of the resulting DNA fragments. The DNA fragments (all of which are synthesized from a single primer site) are then ordered by length to determine which bases are located at which sequence positions. Historically, RNA and DNA sequences were determined by chemical fragmentation techniques, such as the Maxam–Gilbert method, or enzymatic fragmentation, such as various tRNA sequencing methods. A number of variants of this basic scheme have been proposed, such as the cyclical removal or addition of single bases at the end of the sequenced chain.

This article focuses on the second of the three principal sequencing approaches, the use of sequence-specific hybridization to determine primary DNA structure. The process takes advantage of one of the basic biochemical processes of life, the molecular specificity of pairing between two complementary DNA strands. Over the past decade, the use of oligonucleotide probes to sequence or fingerprint unknown DNAs by such hybridization methods has proved to be a highly potent and versatile way to obtain valuable genetic information.

Chemically synthesized oligonucleotides of known sequence allow a fast and informative hybridization search of a DNA sample, a process that is essentially similar to a keyword search of text by an Internet browser. Large sets of probes may be used to assemble an entire sequence, or smaller sets to obtain a “fingerprint” or “sequence signature” specific for a particular DNA. This article reviews the history, principles and experimental applications of DNA sequencing and fingerprinting by hybridization, and describes in detail several studies that demonstrate its tremendous potential as a method of analyzing individual genes or entire genomes.

2 ORIGINS OF SEQUENCING BY HYBRIDIZATION

Nucleic acid hybridization is the basis for all SBH methods. Hybridization is the sequence-specific process in which two polynucleotide chains recognize and bind one another at complementary sites. In 1960, Doty and colleagues at Harvard discovered that DNA molecules that have been denatured by heat or chemical treatment to form single-stranded chains can precisely pair or renature under the right reaction conditions. Specificity of pairing is determined by base complementarity rules in which As from one chain bind to Ts in the other, and Gs bind to Cs.

Initial applications of hybridization in molecular biology (for example colony or Southern blot hybridizations) used nucleic acid probes longer than 50 bases that were derived from natural sources. The specificity and sensitivity of these reactions are such that sequences present at one part in a million can be readily detected. It is not
sequencing and fingerprinting DNA by hybridization

necessary for all bases in such a double-stranded hybrid to match perfectly; up to 1–2% mismatched bases may occur without affecting the strength of hybridization. The current widespread use of hybridization methods to identify samples containing previously isolated sequences is possible because natural sequences (i.e. genes) within a genome typically differ by far more than a few percentages in thousands of bases.

During the late 1970s and early 1980s powerful new research tools were developed to unravel the intricate sequences of DNA molecules. Caruthers and other researchers discovered ways to more efficiently synthesize specific DNA molecules on columns by stepwise addition of nucleotides. These automated DNA synthesizers made possible the production of large numbers of specific oligonucleotides. In a parallel development, Bruce Wallace pioneered the use of such oligonucleotides as hybridization probes to confirm the existence of complementary sequences in target DNAs.

As tools for detecting complementary sequences within a target DNA, oligonucleotide probes proved to be more sequence-specific than longer, natural probes. Wallace demonstrated that oligonucleotide probes 11–17 bases in length can be used to accurately detect single base mutations in defined DNA targets dot-blotted on a membrane. He showed that such probes can be used to discriminate between perfect probe–target duplexes and those containing a single internal base mismatch.

Several years later, Saiki et al. developed a “reverse dot blot” method of screening patient DNA samples for known mutations using oligonucleotide probe arrays. The method relies on an array of defined oligonucleotides designed to complement known mutations and corresponding wild-type sequences in a given gene, such as the human β-globin gene. Patient samples enriched in the particular gene sequence are then tested for hybridization against the array under conditions in which the formation of duplexes with an internal base mismatch is minimized. Positive hybridization of one probe (or two probes in the case of heterozygotes) confirms the existence of the mutation.

These early research developments provided basic research tools that were later used in developing methods for fingerprinting and sequencing DNA by oligonucleotide hybridization. They ensured essentially limitless supplies of oligonucleotides of any pre-specified sequence, and established the experimental conditions suitable for specific full-match hybridization using either target DNA or oligonucleotide probes bound to a support.

In 1986, Poustka and Lehrach demonstrated that oligonucleotide hybridization can play a role in the field of DNA mapping. Their work showed that positive hybridization of an oligonucleotide to a cloned genomic fragment gives essentially the same mapping information as is provided by obtaining a single DNA band when cutting a cloned DNA with a restriction enzyme. In each case a specific short sequence is identified within the test DNA. With oligonucleotide hybridization, the identified sequence is identical in length and complementary in sequence to that of the oligonucleotide probe. The authors showed that hybridization “fingerprints” obtained with a set of short DNA probes can be used to identify overlapping cosmid clones sharing portions of their DNA.

In 1987, as a culmination of oligonucleotide applications in DNA analysis, Drmanac and Crkvenjakov first proposed and later patented the method of SBH, in which the sequence of a DNA fragment is determined by hybridization with a sufficient number of short oligonucleotides of known sequence. The sequence is assembled from the subset of positively hybridizing probes detected by hybridizing a set of overlapping probes with the target DNA. The researchers presented an algorithm for reconstruction of DNA sequences as complex as the human genome that established the relationship between length and number of probes to length and number of clone fragments from the DNA being sequenced. Hybridization of labeled probes to large arrays of clones was proposed as a method for sequencing complex genomes. Like the polymerase chain reaction (PCR) method, SBH radically expanded potential applications of the hybridization reaction. SBH is also thought to be more suitable for automation than classical sequencing methods.

Within a year of Drmanac and Crkvenjakov’s patent application, other research groups presented variations of this new sequencing process. Bains and Smith examined the process of sequence reconstruction from tetramers. In a 1988 patent application, Southern proposed a method for combinatorial in situ synthesis of complex oligonucleotide arrays on glass and hybridization of DNA to the array for mutation detection and complete sequencing. Lysov et al. also proposed SBH using an array of deposited oligonucleotides.

3 PRINCIPLES OF SEQUENCING BY HYBRIDIZATION

3.1 Hybridization Search Principle

SBH shares interesting parallels with conducting a computer search of a text file for a particular word or a phrase. In each case, a large string of characters is probed with a specific shorter string to detect matching sequences. In a computer text search, the search string or strings (key words) are used to browse a large Internet or local database to identify the subset of specific
Figure 1 Hybridization search of a DNA library. The schema depicts hybridization sites for four 5-mer oligonucleotide probes (shown in color) in four target DNA samples, as well as the resulting data pattern. Each DNA has a specific pattern reflecting the distinct subset of positive probes that hybridize with it. However, a hybridization search identifies only which probes hybridize to each sample, without indicating the order in which probe binding sites occur. For example, the result for the first sample is “missing green probe,” and for the fourth sample “only green and yellow probes positive.” The presence of two green probe binding sites in DNA sample 4 would not be detected unless hybridization intensity scores were evaluated instead of simple presence/absence data, as discussed in section 8. These “presence/absence patterns” may be used to identify the DNA (oligonucleotide fingerprinting) or, in combination with similar data from many overlapping probes, to determine its complete sequence.

3.2 Probe Overlap Principle

The first potential probe binding site in a DNA chain starts at the first base and extends for the length of probe. The second probe binding site starts at the second base and overlaps the first probe binding site, less one base.
This means that if a complete (or sufficient) set of probes is tested, the end of each positive probe overlaps with the beginning of another positive probe, except in the case of the last positive probe in the target. This situation is illustrated in Figure 2(a), which shows the results of a hybridization search of a short 16-base DNA sequence with all 1024 possible pentamers. Positive hybridizing probes are indicated in boxes. Using the OP, the positive binding of just 12 of the 1024 possible 5-mer probes unambiguously determines the sequence of the target DNA (see Figure 2b). In each sequence assembly cycle, four potential overlap probes are checked. Starting with a positive probe AAATC, the next positive overlapping probe to the right may be AAATCA, AAATCC, AAATCG or AAATCT. Of these probes, only AAATCG is found to be positive and is used for further assembly. The cycles are repeated in both directions until all positive probes are incorporated and the complete sequence is assembled. By extension, the same process applies to a longer DNA target if enough probes of appropriate length are used to identify uniquely overlapped strings within it.

The use of overlapping positive probes is a key aspect of SBH methods. The OP allows the identification of sequences within a target DNA that are longer than any of the probes used in the assembly process. Probe overlap allows indirect assignment of one out of four bases incorporated and the complete sequence is assembled. By extension, the same process applies to a longer DNA target if enough probes of appropriate length are used to identify uniquely overlapped strings within it.

The information needed to solve branching ambiguities is directly provided by using a reference gene sequence when assembling gene sequences from individual patient samples. When a reference sequence is known, the maximal read length in bases may be extended to approximately one-tenth the number of probes used (Table 1). To sequence human and other complex genomes (over 3 billion base pairs) as a single sample, about 70 billion 18-mer

\(^a\) The number of possible oligomer probes increases exponentially as a function of probe length. Short probe sequences (3- to 4-mers) occur so frequently in a target DNA that their use in SBH experiments is impractical except for the shortest DNAs.

\(^b\) The “basic read length” is that target length which, for a given probe length, has a 95% chance of unique assembly. The length is very approximate for probes shorter than six bases.

\(^c\) The “enhanced read length” is that target length which provides an average about 10% positive and 90% negative probes and less than one end-mismatched binding site per probe.

The use of overlapping positive probes is a key aspect of SBH methods. The OP allows the identification of sequences within a target DNA that are longer than any of the probes used in the assembly process. Probe overlap allows indirect assignment of one out of four bases incorporated and the complete sequence is assembled. By extension, the same process applies to a longer DNA target if enough probes of appropriate length are used to identify uniquely overlapped strings within it.

Because the sequences of DNA molecules are nonrandom and irregular, statistical artifacts arise that must be addressed in SBH experiments. Even when the lengths of DNA targets and probes are selected to achieve a statistical expectation that each probe sequence occurs no more than once in the target, so-called “branching ambiguities” can occur.\(^10,11\) Take the case of three probes that positively hybridize to a target DNA: TAGA, AGAC and AGAT. Both the second and the third probes overlap with the first probe, sharing the bases AGA and giving extended sequences TAGAC and TAGAT respectively. Owing to the occurrence of the sequence AGA in both the second and third probes (e.g. because of double AGA occurrence in the target), there is not enough information available to decide which of the two probes is actually the one that overlaps with the first probe in the sample. Sequence assembly can thus proceed along either of the two branches, only one of which is correct.

By using all probes of a given length (as in Figure 2a), a researcher can unambiguously determine a target sequence, provided the target DNA is short enough that most overlap sequences occur no more than once. The only other exception to this rule is tandem repeat regions (e.g. AAAAAAAAAAA, ACACACA-CAC) that are longer than the probe length. In such cases, the exact length of these repeats may be determined by use of a special subset of longer probes. Longer targets may require longer probes for unambiguous sequence determination. Table 1 shows the exponential increase in the number of possible probes as a function of probe length. A variety of ways have been proposed to increase the read length with a given set of probes, or to reduce the number of experimental probe/target scores needed to sequence a target DNA. These include the use of pools of probes, competitive hybridization and overlapped clones\(^10,11\) and binary\(^15\) probes, continuous stacking hybridization\(^16\) and the simultaneous sequencing of similar genomes.\(^17\)
Figure 2  Probe overlap principle (OP). (a) Rare but overlapped positive probes. Hypothetical SBH experiment showing a 16-base DNA sample hybridized with the complete set of 1024 5-mer oligonucleotides. Probes are written in the 5′−3′ direction, and are sorted alphabetically in vertical columns. Positive-binding probes are indicated in boxes. The sequences of positive probes complement the strand present in the experiment and are identical to its complementary strand. The first binding from the above SBH experiment are used to assemble the target DNA sequence. In this case, assembly starts with the first positive probe in the alphabetical order with five overlapping probes (seen as vertical columns of five letters). In general, the number of overlapped probes reading each base equals the number of bases in the probe.
probes would be needed. With appropriate detection sensitivity and process miniaturization this astonishing task may someday be accomplished in a single hybridization experiment. SBH may be the only sequencing method that has the capacity for whole genome analysis in a single reaction.

4 VARIATIONS OF THE SEQUENCING BY HYBRIDIZATION METHOD

Three basic variations of the SBH method have been developed, as illustrated in Figure 3. These are discussed below.

4.1 Format 1 Sequencing by Hybridization

Format 1 SBH involves using an array of target DNAs exposed to a single labeled oligomer probe or small probe pool in a hybridization step. After washing to remove unbound probe, arrays are scored for signal intensity. As shown in Figure 3, probes that do not match (or only partially match) the target are removed by washing. A subsequent more stringent wash is then used to remove hybridized probe, leaving the array ready for the next hybridization cycle. Probes are applied consecutively to a single array (or replica arrays) of
In the early 1990s, Drmanac and each base. All probes a fraction of the target molecules has to be cut covalent bond by the enzyme ligase. This method requires and each positive hybridization is converted into a stable interaction with the abutting strand of duplex DNA, hybridization of target DNAs is facilitated by a stacking of duplex anchored DNAs with single-stranded tails. The not end-attached single-stranded molecules, but consist of not end-attached single-stranded molecules, but consist of duplex anchored DNAs with single-stranded tails. The hybridization of target DNAs is facilitated by a stacking interaction with the abutting strand of duplex DNA, and each positive hybridization is converted into a stable covalent bond by the enzyme ligase. This method requires very precise sample fragmentation. To be able to score all probes a fraction of the target molecules has to be cut at each base.

4.2 Format 2 Sequencing by Hybridization

In Format 2 SBH, a set of probes is attached in an array pattern on a support. A labeled, fragmented DNA sample is then hybridized to the probe arrays. The sample DNA sequence is assembled from the set of positive probe–DNA hybrids that remain after unhybridized DNAs are removed by washing. A disadvantage of Format 2 SBH is that a large variety of probe–DNA hybrids with different thermodynamic stabilities is formed and scored in a single hybridization reaction. A variant of Format 2 SBH (see Figure 3) was proposed by Broude et al. in 1994. In this variation, probes are not end-attached single-stranded molecules, but consist of duplex anchored DNAs with single-stranded tails. The hybridization of target DNAs is facilitated by a stacking interaction with the abutting strand of duplex DNA, and each positive hybridization is converted into a stable covalent bond by the enzyme ligase. This method requires very precise sample fragmentation. To be able to score all probes a fraction of the target molecules has to be cut at each base.

4.3 Format 3 Sequencing by Hybridization

In the early 1990s, Drmanac proposed Format 3 SBH, an advanced combinatorial method capable of scoring extremely large numbers of probes. Two sets of probes are used in Format 3 SBH (see Figure 3). One set of unlabeled probes is covalently bound to the support. An unlabeled target DNA sample is then hybridized to the bound probes, in the presence of a second set of labeled probes and DNA ligase or another coupling agent. When the labeled and unlabeled probes hybridize to the target DNA at precisely adjacent positions (see Figure 3) they are joined to form a labeled two-probe construct covalently bound to the support. Hot washing removes any labeled probes that are not ligated, as well as the target DNA, leaving only the two-probe constructs to be scored as positive signals. This format allows combinatorial scoring of a large number of probes by preparing two small sets of short probes. For example, over 1 million 10-mers can be scored using just two sets of 1024 5-mers. The combinatorial aspect arises from the arrangement of subarrays of bound probes in a larger superarray, each subarray being exposed to one labeled probe or probe pool in a single hybridization reaction. The superarray may contain as many subarrays and hybridization chambers as there are labeled probes or labeled probe pools to allow their simultaneous scoring. The use of two short probes, a unique feature of this SBH format, provides better discrimination than would be achieved with other formats using probes twice as long. In addition, there is no need to cut the target DNA at each base pair, as is required in the Format 2 ligation approach.

In all SBH formats, a DNA polymerase elongation reaction may be used in addition to probe hybridization in the scoring process. In this case, unlabeled probes act as primers, and are extended by DNA polymerase by at least one labeled base after hybridization. By using four different labels, one for each of the four dideoxy nucleotides, probes may be specifically extended by one base before final scoring.

5 APPLICATIONS

Oligonucleotide hybridization is a flexible method of screening and sequencing DNA samples. By selecting appropriate combinations of probes and samples, oligonucleotide hybridization can be used for a wide variety of applications ranging from DNA fingerprinting to complete sequencing. There are five general types of applications for oligonucleotide hybridization (Table 2):

<table>

* The numbers of probes used varies dramatically depending on the application, from ten to a few hundred in simple DNA fingerprinting to tens of thousands in some de novo sequencing applications. Each application takes advantage of one or both of the basic principles that underlie SBH methods: the search principle (SP), in which the presence of complementary oligonucleotide sequences within a target DNA is determined, and the OP, in which overlapping positive probes are used to assemble a target sequence.
- clone contig mapping over a wide range of clone lengths;
- clustering, motif searching, or partial sequencing of cDNAs;
- scoring known polymorphisms and mutations, including single nucleotide polymorphisms (SNPs);
- individual DNA sequencing for discovering novel polymorphisms or mutations;
- de novo sequencing.

The number of probes used and the informational principles behind each application vary widely depending on the experimental goals. Only about 100 probes are needed to obtain clone contigs and cDNA clusters, procedures that involve only the hybridization SP. For partial sequencing and detection of known mutations the number of probes used may range from a few oligonucleotides in some simple applications to thousands in others. When overlapping probes are used to sequence DNA, the probe OP is employed, in addition to obligatory use of the hybridization SP. For discovery of novel mutations or polymorphisms, both search and OPs are used, and the number of probes used may range from complete sets of 4-mers up to complete sets of 20-mers. Another possibility is to use incomplete sets of longer probes, ranging from 7 to 30 bases. Nucleic acid samples can vary from a few hundred bases in length, such as short PCR products, to lengthy cellular mRNAs or genomic DNAs. Each of these five basic oligonucleotide hybridization applications is discussed in detail below.

5.1 Clone Contig Mapping Over a Wide Range of Clone Lengths

Oligonucleotide hybridization can be used to identify overlapping clones that contain identical sequence strings. Since overlapping cosmids share common sequence regions they should show significantly larger numbers of shared positive probes than would be statistically expected from a randomly selected set of oligonucleotides. The authors demonstrated that a set of 100 randomly chosen 12- to 16-mer oligonucleotides is generally sufficient to identify and order cosmid clones if the neighboring overlapped clone pairs share more than 30% of their sequences. The first real application of this idea was the construction of cosmid maps of a yeast genome in 1993. This method, which can be used for long-range mapping of large cosmids or BAC (bacterial artificial chromosome) clones, relies on using a set of 100–200 12- to 16-mer oligonucleotides and additional longer repetitive DNA probes.

Long-range maps of such cosmids and BACs, obtained either by the above-described application of oligonucleotide hybridization or by classical restriction mapping techniques, are necessary for gene cloning and genomic sequencing projects. The BAC or cosmid clones chosen from the maps are generally subcloned into 1- to 5-kb fragments suitable for gel sequencing or SBH. These subclones can be either sequenced randomly in a shotgun approach by gel, or fingerprinted using Format 1 DNA arrays to map or group highly redundant clones. This fingerprinting procedure typically reduces the number of redundantly sequenced clones by 3- to 6-fold, resulting in substantial cost and time savings. The map can be constructed by obtaining sequence signatures with a few hundred 7-mer probes from the sufficient number of 0.5- to 2-kb subclones (20 equivalents of the map length).

5.2 Clustering, Motif Searching, and Partial Sequencing of cDNAs

DNA sequence signatures provide a powerful tool for identifying new genes. Drmanac originally proposed obtaining sequence signatures in 1990, using Format 1 as an efficient, high throughput method for characterizing cDNA libraries. Clones arising from the same genes are clustered together based on their similar hybridization signatures. A single representative of each cluster may then be sequenced, dramatically reducing the number of clones that must be sequenced compared to the randomly selected, repetitive DNA sets obtained by the expressed sequence tags (EST) method. This hybridization method has been used extensively and is discussed in detail in section 9. At Hyseq, Inc., by processing over 1 million clones per month in various projects, hybridization signatures for over 15 million cDNA clones have been generated and tens of thousands of novel, rarely expressed genes discovered.

Using a large probe set, samples whose sequences are already present in databases can be identified without resorting to complete sequencing. A more narrowly directed set of probes can be used to detect coding sequences for any and all variants of a protein motif present in cellular mRNAs. The use of incomplete sets of probes to interrogate only certain segments or types of sequences in the target is called partial SBH.

The gene clustering data obtained from Format 1 SBH experiments are also used to accurately measure gene expression in a given cell or tissue. The size of a cluster for a specific gene is a direct measure of that gene’s activity within the test tissue or cell line. This method provides new breadth and precision in monitoring gene expression in any tissue or cell line from which a cDNA library has been prepared. No previous knowledge of which genes are expressed or their sequences is necessary for the analysis. The method allows statistically verifiable results to be obtained by directly counting rarely expressed genes for the first time. Comparative analysis of cDNA
libraries from diseased and normal tissues provides a comprehensive list of which genes are up- and down-regulated in the disease process.

Lockhart et al. applied oligonucleotide arrays to measure the expression of previously discovered genes that had been sequenced. In this application, adjacent cells in an array contain a variety of 15- to 25-mer oligonucleotides. For example, a 4000-gene array might contain 80 000 different oligonucleotide spots, with roughly 20 spots corresponding to each mRNA. Manufacture, hybridization, and scoring of these miniaturized arrays are analogous to those used in the sequencing applications described below. When cellular mRNA mixtures are hybridized to the probe array, the signal strengths obtained are in theory proportional to the amounts of specific mRNAs in the mixture, and hence provide a measure of gene activity. Researchers at Affymetrix, Inc. (Santa Clara, CA) have recently reported oligonucleotide arrays representing 30 000 mouse and 40 000 human genes selected from public databases.

5.3 Detection of Known Polymorphisms and Mutations, Including Single Nucleotide Polymorphisms

Since 1979, various hybridization methods have been developed to detect and identify known gene mutations and polymorphisms, including SNPs. An electronic variant of oligonucleotide probe arrays has been developed to detect the presence of known mutations or specific microorganisms in environmental samples. In this method, DNA from lysed bacteria is concentrated and fragmented, then hybridized to a microarray of sequence-specific oligonucleotide probes.

The large arrays currently used in both Format 1 and Format 2 applications allow simultaneous scoring of many independent sequence sites in complex nucleic acid samples. The hybridization search process, with its random parallel access to all potential target sequences, determines which sequence variant or allele is present at each interrogated site. For instance, single arrays can be designed to interrogate 1000 potential mutation sites within 100 genes using complex cDNA mixtures obtained from a single patient. For the first time, such methods allow development of DNA diagnostic population screens.

One approach being vigorously pursued in human genetic mapping involves scoring thousands of SNPs from individual members of affected families or selected population samples. Format 1 arrays of 55 000 pools of 10 to 100 DNA amplicons prepared from individual genomic DNA samples allow extremely efficient population genotyping of known polymorphisms or mutations. Consecutive hybridization of a few probes per allele permits the scoring of millions of genotypes per day. In a complementary approach, Format 2 SBH arrays have been developed that allow simultaneous scoring of 500 SNPs for each individual patient using a set of overlapped probes for each allele.

A comprehensive survey of defined functional SNPs might comprise about 1 million genomic sites that exhibit greater than 1% polymorphism frequency and are known or expected to influence phenotype. Such a survey could be used to obtain an almost complete diagnosis of the health of what is arguably the body’s most important organ, the human genome. This type of patient genome description or “Genogram” should prove to be of enormous medical importance. With proper miniaturization, for example using arrays of micron- or submicron-size beads, Format 3 SBH is probably the best-suited technique for this application, which would require high-fidelity testing of several million probes more than 10 bases in length.

5.4 Discovery of Novel Polymorphisms or Mutations by Individual DNA Sequencing

This application usually requires large or complete sets of oligomer probes. A common procedure is to use all probes corresponding to a given reference sequence. In 1991, Strezoska et al. demonstrated the potential of using Format 1 SBH to confirm the absence of base changes in an individual DNA sample. Using 100 octamers corresponding to a known 100-base sequence, the researchers were able to accurately assemble the test sequence based on the hybridization results obtained. The use of several overlapping probes to test each base assured high accuracy. In a more advanced application, Drmanac et al. used a complete 7-mer probe set to accurately sequence over 10 000 bases of p53 exon DNA from a number of samples. The accuracy, turnaround time, and throughput of this Format 1 application make it suitable for the large sample volumes used to detect rare polymorphisms. The use of complete sets of probes allows the sequencing of any gene, and can determine virtually all types of mutations and polymorphisms. This work is discussed in detail in section 9.

Southern et al. demonstrated the use of Format 2 SBH to sequence 24-base model targets using a 256-member array consisting of all possible 8-mer probes made up entirely of purines. Subsequently, researchers at Affymetrix, Inc., developed Format 2 SBH methods designed primarily for sequencing certain variants of individual DNA samples when a prototype sequence is known. Using lithography, they produced miniaturized arrays consisting of sets of 18- to 25-mer oligonucleotide probes that are designed to detect unchanged sequences and those with single base substitutions. Probes are selected so that each base in the target sequence is covered...
by four oligonucleotide probes that are identical except for one centrally placed base that varies in each of the four oligonucleotides. Large probe arrays may be able to analyze DNA segments several kilobases in length.\(^{(36)}\) Since this method uses a very select, partial set of long probes, some mutations may be detected but cannot be precisely sequenced, particularly in the case of insertion mutants. Sequence-specific arrays have been constructed and used to sequence the HIV clade B protease, BRCA1, and ATM genes.\(^{(37-39)}\)

Broude et al.\(^{(18)}\) proposed the development of universal microarrays containing duplex DNA anchors with all possible single-stranded \(n\)-mer tails. This variant of the Format 2 SBH procedure involves ligation of the target DNA to matching probes. Gunderson et al.\(^{(40)}\) used this method to sequence approximately 1 kb fragments of the HIV pol and cytochrome \(b\) genes in test DNA samples. The researchers used complete arrays of 8-mer and 9-mer probes.

Hyseq, Inc., has developed the HyChip\(^{TM}\) system for accurate complete sequencing of any candidate gene (including heterozygotic sites) in individual genomic DNA samples and discovery of all types of polymorphisms and mutations. The HyChip\(^{TM}\) system scores all possible 10-mers (1048576 combinations) using a Format 3 SBH ligation procedure involving two sets of 5-mer probes.\(^{(39)}\) A sequence read length of 2000 bases has been demonstrated. (S. Drmanac et al., paper in preparation).

The examples above demonstrate that SBH can provide accurate and efficient polymorphism discovery, information that is of critical scientific and medical importance. There is a growing need to sequence most of the genomic DNA of perhaps 1000 individuals to discover significant human polymorphisms (those with 1% frequency or greater) for correlation studies, and to develop Genogram tests for diagnosis.

### 5.5 De Novo DNA Sequencing

De novo sequencing of complex genomes is the most challenging SBH application.\(^{(11)}\) Successful sequencing of different DNA fragments has been reported by some researchers. Drmanac et al.\(^{(41)}\) demonstrated the accuracy of the SBH Format 1 technique by sequencing unknown short primate DNA sequences using a set of octamer oligonucleotides in a blind test. The probe set contained both exact match and mismatched probes and was tested against three 116 base pair homologous regions obtained from different primate T-cell receptor loci. Exact sequences were determined without a single error. False-positive probe hybridization was found to occur infrequently and was easily corrected due to the high data redundancy inherent in the SBH method.

In 1996, Hyseq, Inc., researchers sequenced nearly a million bases of cDNA clones using a combination of data obtained from single-pass gel sequencing and from a complete set of 7-mer probes scored by Format 1 SBH (unpublished data). Blind tests of Format 3 SBH demonstrate the reliability of using hybridization and ligation of adjacent probes to sequence unknown DNA samples (S. Drmanac et al., paper in preparation). By scoring all possible 10-mers (obtained by ligating two 5-mers) using HyChip\(^{TM}\) 5-mer arrays, sequences as long as 800 bases may be assembled directly from the hybridization data (see Table 1). In the future, scoring longer probes (e.g. 14-mers) using pools of distinctly labeled 6- to 7-mer probes and miniaturized arrays of 7- to 8-mers may provide de novo read lengths of 10 kb or more, a task that is difficult if not impossible to achieve with nonhybridization sequencing methods.

### 6 BIOCHEMISTRY

#### 6.1 Sample Preparation

Most current SBH applications, with the exception of Format 2 expression studies, use nucleic acid samples ranging in length from 200 to 2000 bases. Initial DNA samples are typically obtained by cloning or PCR. Some samples, such as multiplex PCR preparations, are mixtures of fragments, with a total length of up to several kilobases of DNA. PCR is the dominant preparation method, due to its ease of use, reproducibility, and high yield. Plasmid and phage preparations have also been used.\(^{(41,42)}\) High-throughput PCR procedures have been developed to create the large DNA arrays used in Format 1 SBH applications.

Figure 4 shows the outcome of PCR preparations of 22 genomic DNA samples obtained from individual patients. A 10\(^4\)-fold amplification of as few as 100 copies of a ~1 kb ApoB gene segment was achieved, with only a two-fold yield variation between samples. Negative controls with no patient DNA have undetectable signals. Cross-contamination of up to 5% in the final arrayed samples can be tolerated due to the small contribution (below the level of mismatch signals) of such contaminants to the signal.

Throughputs of up to 50000 PCR reactions per day are routinely achieved for current Format 1 SBH gene discovery projects.\(^{(43)}\) Initial samples for PCR preparations may consist of cloned DNA in bacterial plasmids or purified genomic DNA. The small amounts of proteins and other contaminants present do not hinder the hybridization reaction, allowing simplified, automated sample preparation.

In order to prevent secondary structure formation within the target DNA prior to exposure to probes in Format 1 SBH, denatured target strands are anchored...
to the substrate by a pseudo-covalent bond every 30–50 bases, thus preventing renaturation. In Formats 2 and 3 SBH, the target DNA is fragmented into small pieces about the size of the probes and then denatured, to assure that internal secondary structures within the target are less stable than probe–target duplexes. Under the excess probe conditions used, such target–target duplexes are simply out-competed kinetically. Owing to its amenability to fragmentation and labeling, the final target in most Format 2 SBH applications is RNA synthesized from clone inserts.

6.2 Probe Preparation

Oligonucleotide probes may be synthesized quickly and accurately on modern DNA synthesis machines, with thousands of specific, high-quality probes produced in a few days. In some applications, additional purification of oligonucleotides by gel or column chromatography is necessary. No such purification is necessary for Format 1 procedures. In commercial batches of several thousand unique probes, less than 5% typically prove to be unsuitable for hybridization due to impurity or improper synthesis. In Format 2 SBH (especially when ligase is used) and Format 3 SBH, probe purification is appropriate to avoid shorter products. In the case of in situ synthesis of probe arrays, no purification procedure is possible, creating potential quality control (QC) and reproducibility problems between arrays. An additional concern with in situ synthesized miniaturized arrays is the density of probe molecules per spot. The density of usable probe strands per unit of surface area is a critical factor in determining signal strength. Too few or too many probes (which prevents target access) results in low or undetectable signals.

For a variety of reasons, pools of probes are sometimes synthesized by incorporating more than one type of base in a single base-addition cycle. With such degenerate probes, the goal is that equimolar incorporation of all bases occurs. To assure this condition, it is necessary to premix bases in proper ratios instead of depending on correct uptake by instrument pumps.

Most current SBH applications use natural bases. Modified bases may be used to equalize hybridization strength for G + C-rich and A + T-rich probes, and to modulate the overall stability and specificity of base pairing. Many initial studies are underway to test how these factors are affected by different chemical modifications of natural bases. The base modifications must be compatible with DNA ligase and polymerase or other enzymes if these enzymes are part of the probe-scoring process.

6.3 Array Chemistry

In preparing DNA arrays, attachment of strands to the solid substrate is maximized to reduce the quantity of soluble DNA or label needed to produce a strong signal. In addition, nonspecific binding of labeled stand to either the substrate or bound probes is minimized to reduce the background signal. This is achieved by choosing inert substrates or adding appropriate components of hybridization buffers that minimize or compete for nonspecific binding sites. In Format 1 SBH, the nylon membranes used for making arrays are typically a mesh of fibers, allowing three-dimensional binding via pseudo-covalent bonds. Subsequent ultraviolet cross-linking of T bases produces covalent interstrand bonding, leading to retention of a higher proportion of input strands. Approximately 60–90% of the initially bound DNA is retained, even after repeated cycles of hybridization and washing. In Format 2 SBH, the substrate is usually flat, nonporous glass. The density of bound probes is a direct function of the number of activated sites per unit surface suitable for attachment of either pre-made oligonucleotides or initial monomers used in subsequent in situ synthesis. The probe density achieved is a function of surface activation and coupling chemistry. Other potential substrates include polyacrylamide gel-coated glass or micro beads.

6.4 Labeling

In preparing DNA arrays, the soluble DNA strand in an SBH array experiment, whether probe or target DNA, is usually labeled to allow scoring of hybridization events. Any part of the strand
may be labeled, but typically the terminal base of a probe or target DNA fragment is chosen. The labeling procedure may be enzymatic or chemical. For instance, in Format 1 SBH applications, polynucleotide kinase adds a $^{33}$P-labeled phosphate group on the 5' end of oligonucleotides, while in Format 2 SBH applications, RNA polymerase is used to incorporate fluorescent-labeled RNA bases to create a multiple chromophore attached to the target DNA. Labeled groups can also be added during chemical synthesis of oligonucleotides. The most common labels are radioactive or fluorescent tags that are readily quantified by advanced detection devices such as Phosphoimagers (Molecular Dynamics, Sunnyvale, CA) or fluorescence scanners (GSI Lumonics, Inc., Watertown, MA).

Radioactive tagging is the traditional labeling method used in nucleic acid chemistry and is still widely used in Format 1 SBH applications. $^{33}$P has several advantages as a radioactive label for nucleic acids. One is an optimal $\alpha$ particle energy, which provides the rapid, sensitive detection characteristics of higher-energy nuclides, but with the high resolution and added workplace safety of a particle that exhibits minimal air penetration (less than 1 cm). The other advantage is a short half-life, requiring only a 6-month decontamination period for any radiolabeled wastes. $^{33}$P-labeled array spots need to be at least 200–300 µm apart to be successfully resolved, and the lower limit of detection is about 10 labeled duplexes per square micrometer.

Fluorescence labeling can be direct, in which case an organic chromophore is covalently attached to the DNA, or indirect, such as when a tag attached to DNA binds a chromophore-carrying molecule. In either case, chromophore-labeled duplexes are excited by light of the proper wavelength and the resulting emission signals are measured by a fluorescence detector. Although detection of a single molecule’s fluorescence is theoretically possible, in reality both reader sensitivity and background fluorescence are limiting factors in using fluorescent labels for SBH. Signal detection limits with advanced commercially available readers are approximately 1–10 chromophores per square micrometer. Direct fluorescence has been the labeling method of choice in miniaturized SBH formats, although mass spectrometry is becoming increasingly popular.

### 6.5 Discriminative Hybridization

#### 6.5.1 Hybrid Stability

SBH is possible because the specificity of binding between single-stranded DNAs and complementary oligonucleotide probes (expressed as binding strength or recognizable duplex structure) can be used to discriminate matched from mismatched probes. The experimental parameters used to influence binding/dissociation generally include hybridization and wash temperatures, wash time, and other solution conditions such as salt concentration (see Wetmur for a more detailed treatment). In the case where one of the strands is attached to a solid support, the dissociation temperature, $T_d$, at which 50% of duplexes have dissociated is used as a measure of hybrid stability. Figure 5 shows DNA–probe dissociation curves for a typical full-match 8-mer probe and two different single-mismatch 8-mer probes as a function of temperature. The separation of the curves suggests that near $T_d$ for a mismatched probe hybrid, most full-match probes remain bound to the target DNA, allowing discrimination of the two probes.

In general, both thermodynamic and kinetic factors influence the binding and dissociation of DNA–probe hybrids, but it is generally kinetic dissociation rates that are used to discriminate between matched and mismatched probes. In free solution, $T_m$ (the temperature at which 50% of possible duplexes are melted) is a linear function of GC content. $T_m$ may be converted to $T_d$ by a simple equation. In oligonucleotide hybridization, $T_m$ is a more complex function of actual base sequence, and is dependent on $\Delta G$, the standard free energy. For an 8-mer hybrid, $\Delta G$ is dependent on three factors: a $\Delta G$ sum of nearest-neighbor contributions for seven (of 16 possible) dinucleotide interactions present in the probe, a temperature-independent initiation component, and a dangling end component. Measured values for the various

![Figure 5](image-url)  
**Figure 5** Dissociation curves of typical 8-mer probes. Graphs represent percentage of denatured hybrid after a 1-min wash at a given temperature. At 15 °C, the fraction of melted hybrids for mismatched probes is two to three times higher than that for full match probes. Probe-DNA hybrids formed with full match probes tolerate higher wash temperatures or longer wash times than mismatched probes, allowing experimental discrimination by manipulating wash temperature and/or wash time.
component contributions have been reported.\textsuperscript{(45,46)} An internal mismatch leads to a decrease in two nearest-neighbor contributions, while an end mismatch results in a decrease of one nearest-neighbor contribution. The stacking interaction of two abutting but noncovalently linked probes hybridized to a longer complementary strand generally has the same effect on stability of the longer probe as lengthening it by one base.\textsuperscript{(44)} Use of this stacking effect in SBH has been proposed by Khrapko et al.\textsuperscript{(16)}

Dangling end contributions are dependent on the single-stranded DNA sequences that surround the DNA–probe duplex, leading to the observation that the same short duplex can have a different stability in different sequence settings.\textsuperscript{(41)} While thermodynamic measurements on synthetic model duplexes generally agree with the theory, no precise prediction of hybridization signal strength has been possible with natural target DNAs. This is due to various sequence context effects on duplex stability or on physical access of probes to binding sites.

Duplex stability (as measured by $T_d$) decreases with shorter probe length. By manipulating target DNA and probe concentrations one can generally maximize the amounts of remaining duplex product at sub-room temperatures, even for very short probes. The sensitivity of detection provided by radioactive- and fluorescent-labeled probes creates a lower practical limit of approximately 5- to 6-base pair duplexes in SBH. In special conditions, such as ribosome binding sites, stable, base-specific duplex binding occurs in codons consisting of only three base pairs. To improve detection and reduce the number of probes needed for various applications, the use of probes with degenerate ends was proposed for fingerprinting\textsuperscript{(47)} and SBH.\textsuperscript{(10,11)} These are pools of probes that share a common core sequence but have one or more varying bases at the ends. For instance, a complete set of octamer probes with a single degenerate base at each end will exhibit the duplex stability of a decamer probe set. Discrimination is also improved, because all mismatches that occur in the core sequence are internal. Such an 8-mer probe set consists of 65,536 probe pools, as opposed to 1048,576 possible decamers.

6.5.2 Discriminative Hybridization

Obtaining sufficient matching signal strength over detection background, and at the same time achieving significant discrimination between match and mismatch signals, are critical goals of the probe hybridization process. Drmanac et al.\textsuperscript{(48)} presented a mathematical treatment of the discrimination kinetics of the SBH process that includes the influence of background signal.

Using equations describing the association and dissociation of DNA–probe complexes, they showed that optimal discrimination, defined as the ratio of amounts of full-match over mismatched duplexes, is primarily determined by wash temperature and time. Based on their analysis and later experimental verification, they concluded that increases in temperature generally reduce discrimination values (Figure 6). Very low temperatures, on the other hand, require an exponential increase in wash time. The ideal conditions for discrimination of short probes (five–nine bases) were found to be an excess of initial hybrid, moderately low wash temperatures, and extended wash times, usually over 15 min.

Using optimized washing conditions, there are no limits on discrimination values if sufficiently large quantities of hybrid (relative to background) are obtained in the hybridization of large quantities of

![Image](https://via.placeholder.com/150)

**Figure 6** Improved discrimination with low-temperature wash. Experimental hybridization images show disproportionate removal of labeled, hybridized probe between full match and mismatch targets as a function of wash time and temperature. To make the phenomenon visually obvious, 50 times more mismatch DNA is used, results in a 100-fold discrimination factor.

target and probe. Figure 6 illustrates 100-fold discrimination achieved in a specially designed test experiment.

There is a thermodynamic explanation for why better discrimination is achieved at lower temperatures and for shorter probes. Discrimination is a function of $\Delta \Delta G$, the difference of $\Delta G$s for matched and single mismatched duplexes. For the same mismatch this parameter is independent of probe length and is inversely proportional to temperature.$^{45,46}$ For example, the TGTAC/gGTAC full-match/mismatch 5-mer pair has the same $\Delta \Delta G$ as the TGTACCC/gGTACCC 7-mer pair. Since longer mismatched probes require higher melting temperatures (which reduces the $\Delta G$ term) such long probes generally exhibit poorer mismatch discrimination than shorter oligomers. For example, $T_d$ values for perfectly matched 14-mer and 20-mers are 41 and 57 °C, respectively,$^{44}$ and their dissociation curves would be displaced far to the right of those for the octamers shown in Figure 3. On the other hand, short probes can be hybridized and washed at much lower temperatures, since short mismatch duplexes can be denatured at such low temperatures. At these temperatures, the $\Delta \Delta G$ term is relatively larger, leading to enhanced mismatch discrimination. As a result of these factors the use of two shorter probes instead of a single longer one in Format 3 SBH results in greatly improved discrimination in scoring probes over 10 bases in length.

The basic low-temperature hybridization and washing conditions developed by Drmanac et al.$^{48}$ are routinely used in most current SBH applications. These conditions usually involve hybridization at 0–15 °C, using increased concentrations of both probe and target to accommodate the decreased stability of short or AT-rich duplexes. Although 15- to 25-mer oligonucleotides (commonly used in Format 2 SBH applications) can be hybridized at room temperature and above$^{7}$ most Format 2 procedures use low-temperature conditions, primarily to reduce the amount of sample required. Many of the procedures and components used in SBH hybridization and washing are derived from traditional molecular biology hybridization applications.

Format 2 SBH arrays require the simultaneous formation of large numbers of duplexes of different stability. This poses the problem of choosing one optimal temperature (or other hybridization conditions) to maximize discrimination among the many duplex types. To address this situation, Khrapko$^{16}$ proposed to measure the differential melting of individual duplexes. This approach is experimentally demanding, and no simple solution to the problem has yet been found. The optimized low-temperature hybridization conditions developed by Drmanac et al.$^{48}$ maximize overall discrimination and the number of different duplexes that give measurable signals. Since different signals may be produced by different probe–DNA hybrids, sophisticated scoring systems that recognize more than a single threshold signal are generally used.

While hybrid stability is predominantly used in SBH experiments to detect the presence of complementary sequences in complex nucleic acid mixtures, other means may be applied to achieve mismatch discrimination. Coupling probes using either a chemical agent or ligase (as in Format 3 SBH) is one method of improving discrimination.$^{19}$ This procedure transforms short-lived complexes into stable, covalently bound products, producing stronger and more uniform signals even under very stringent hybridization conditions. DNA ligases with increased enzymatic specificity may also be used.$^{49}$ Another possibility is to use agents that cut nucleic acid strands at mismatched positions.$^{50}$

7 SEQUENCING BY HYBRIDIZATION AUTOMATION

SBH procedures are generally large-scale analyses that may involve the transfer, storage, and processing of tens of thousands of DNA samples and probes each day. To scale up for such processing, multi-well microtiter plates are used to organize large numbers of dissolved DNA samples or probes. Standard 8 cm × 12 cm plates used in SBH may contain from 96 to 1536 wells. Transfer devices such as robotic pipettors and pin tools are used to create surface-bound arrays or to transfer samples/probes from one plate to another. These transfer devices are arranged in arrays of 8 to 1536 units and can be used to spot samples or probes in arrays on solid supports. The resulting arrays range in size from 100 to 100 000 nucleic acid spots. Electronic bar codes are used to track samples and probes with each transfer step, and to input information in a database. Bar coding eliminates the need for manual recording and tracking and greatly reduces the possibility of labeling error. Figure 7 summarizes the DNA handling and hybridization steps of a typical Format 1 SBH experiment.

Automatic handling of plates containing DNA samples and probes is convenient but not essential, especially when using plates with 384 or more wells. However, high-density plates provide progressively smaller sample volumes (50 µL for a 384-well plate down to 10 µL for a 1536-well plate), which pose potential evaporation loss problems during transfer operations. A variety of techniques have been developed to minimize evaporation and sublimation. These include layering mineral oil over water-based DNA solutions, covering plates with plastic wrap before freezing, and adding glycerol to increase...
viscosity and minimize freezer damage to live cDNA clone cultures.

Arraying more than 100 DNA spots per square centimeter usually involves using tools with precise delivery characteristics mounted on an XYZ robotic station with a consistently repeatable resolution of 10–100µm. Liquid transfer may be accomplished using a variety of physical principles, including active pipetting by hydrostatic or piezoelectric forces, capillary action, or simple surface tension on the tips of pins. Simple pin tools must be “reloaded” after each transfer, while other devices with a reservoir may transfer replicate aliquots of the same sample. Good reproducibility is essential in all arraying procedures, including spot-to-spot transfers from a single channel, channel-to-channel reproducibility within an array, and array-to-array reproducibility. At Hyseq, automated offset printing is used to create a batch of four replicate 55,000-spot arrays on nylon membranes. An 864-pin tool transfers cDNA samples from sixty-four 864-well plates, spotting a few nanoliters of sample with each transfer cycle. This process has been in constant daily operation for over 2 years. Similar procedures are used in many laboratories to create arrays of samples or probes on glass microscope slides.

In situ synthesis of oligonucleotide probe arrays is a computer-controlled photolithographic process in which nucleotides are added sequentially in specific patterns. Specially designed photolithographic masks control the order of light-activated coupling reactions at each array position. This in situ synthesis process may be used to create dense arrays containing over 100,000 probes on a single 1.28 cm² substrate. Significant amounts of shorter oligonucleotide products are produced as by-products of any long probe synthesis. QC procedures on such arrays are often not practical.

Oligonucleotide hybridization procedures are mechanically simple and are easily automated. Robotic equipment used for hybridization must be able to deliver and remove buffers and sample or probe solutions and a thermostatically controlled heating system is needed to control hybridization temperatures. A method of mixing liquid layers above surface-bound arrays may be used if the overall liquid depth is more than 2 mm. The larger the array, the more demanding the requirements for automation engineering. For example, small numbers of microarrays on glass slides can be processed in simple table-top hybridization devices, while Format 1 arrays containing tens of thousands of samples are processed in large robotic stations. The use of XYZ robotic stations for hybridization procedures allows flexible access to multiple hybridization chambers on a single platform. Drmanac et al. used removable partitions on Format 1 SBH filters to create 384 individual hybridization chambers, each receiving a different labeled oligonucleotide probe for rapid parallel hybridization and washing.

The data readout of an SBH experiment is an array of signals corresponding to hybridization strength at each probe–DNA spot. The image is usually generated by scanning instruments and is composed of rows of pixels. Since each dot is represented by 10 or more pixels, a single large array may contain as many as 10⁸ pixels. As described earlier (see section 6.4), owing to the practical limitations on probe and DNA concentrations, scanners must be able to detect between 0.1 and 10 labeled duplexes per square micrometer. Most large SBH applications require high image scanning speed for collection of multiple images per scanner per day. Confocal laser microscopy is generally used to achieve the sensitivity needed for array imaging. For more advanced applications, charge-coupled device (CCD) cameras with 1000 × 1000 or larger pixel arrays may provide the solution if detection sensitivity of less than 10 labeled duplexes per square micrometer is achieved. Such instruments can acquire multiple images per second, resulting in readouts of over 10⁸ pixels per minute.
Future trends in SBH equipment development, particularly in the field of DNA diagnostics, will focus on the design and construction of efficient systems for sample preparation, hybridization, and data readout.

8 DATA ANALYSIS

All current hybridization-based fingerprinting and sequencing applications are based on arrays. The initial data obtained from each unit (DNA or probe spot) in the array is a hybridization signal intensity measured with a detector device. Since individual arrays or sets of arrays may range in size from 1000 up to 1 million array elements, large amounts of primary data must be collected and processed. Automated processing techniques have been developed to handle such large volumes of data. Although user-friendly interfaces have been developed that allow manual intervention in data analysis, the trend in SBH data analysis is to automate the entire process. Information-processing demands of the SBH method can be met by current computer technologies in a cost- and time-efficient manner.

Data analysis consists of four basic tasks, as outlined in Figure 8: (1) sample and probe tracking; (2) image analysis, to transform primary measurements into raw sample/probe responses; (3) normalization and QC of raw data; and (4) analysis of normalized data by application programs to obtain sequence or fingerprint results.

![Figure 8 Flowchart of SBH data processing. Hybridization arrays are scanned to capture signal intensity at all array positions, then analyzed using specialized software to locate each array position (image analysis), and to evaluate and normalize signals. Appropriate sample/probe information is collected by a laboratory information management system (LIMS) and stored in the database. Using LIMS, unsatisfactory data are reported to the laboratory for repeated experiments. Normalized signals and LIMS are then used by other computational programs to assemble sequences, map clones, detect mutations and/or identify target DNAs and report results.](image-url)
The need for precise sample and probe tracking is not specific to SBH applications. Automated laboratory information management systems (LIMSS) have been developed for other genomic and clinical laboratory applications to accurately track sample handling. In Format 1 SBH applications, all microtiter plates, arrays, exposure cassettes, robotic stations, freezers, etc. are bar-coded to allow careful tracking of all sample and probe handling procedures in a central LIMS database. Various programs and user interfaces are used to facilitate both ongoing experimentation as well as proper identification of samples for data analysis. In other SBH formats LIMS procedures are less extensive but still play an important role in data gathering and analysis.

Image analysis for SBH applications has involved the development of specific software packages, since accurate signal processing of spots in predefined arrays (Figure 9) is not a common image analysis application in other technical fields. A pixel image of each hybridized array is generated, with each dot in the array typically represented by 10 to 100 pixels. The first task of SBH image analysis is to define a line grid representing the rows and columns of sample spots in an array. Hybridization images typically do not have positive signals at every unit position in the array. The task of defining this grid becomes progressively more difficult as the percentage of positive spots in the array becomes smaller. Accurately assigning a small percentage of positive spots to an imperfect grid can be accomplished by advanced image analysis programs. Once the grid is accurately established, each spot’s signal is quantified by averaging the signals from pixels covering that spot. Intensely positive neighboring spots may create occasional signal spillover, which may need to be corrected to achieve accurate data analysis.

Normalization and QC procedures maintain the quality and statistical integrity of SBH data. Data normalization corrects for experimental variables such as differences in labeling efficiency of different probes or samples, variations in amount of spotted nucleic acids, and other experimental factors. Other normalization procedures measure internal consistency of duplicate data samples, or compare unknown samples and known controls. QC procedures eliminate data that cannot be adequately normalized, or that remain inconsistent after normalization. Also eliminated are data that do not meet empirically measured reproducibility and quality standards. These built-in QC controls help identify and eliminate problem data resulting from misidentified or poorly hybridized samples, probes, and arrays, allowing portions of experiments to be repeated (for more details see Drmanac and Drmanac').

Application-specific data analysis software is developed for each specific combination of data formats and user needs. Owing to the large size of many SBH data sets, obtaining final experimental results is usually computationally intensive, particularly when data elements require pair-wise comparisons. Specific programs capable of extracting results from normalized hybridization data operate on one of two principles: (1) the normalized signal strength is used directly as a measure of the probability of a full match; or (2) the signal is converted into a discrete positive or negative outcome using a function designed for the specific experimental protocol. Owing to limitations associated with each of these approaches, application programs usually combine both methods. In addition, such programs are equipped with statistical routines designed to compensate for certain levels of false-positive and false-negative data.

The inherent redundancies in SBH data can compensate for surprisingly high error rates that may occur in some low-quality data sets. An “expert system” type of analysis is implemented to process such complex data sets. In this approach, a decision-making tree is developed to partition data based on signal strength or type of probes, and then to apply different criteria for each subset. For example, hybridization signals may be first divided into strong, weak, or insignificant signals, and then statistical tests used to determine positive and negative probes among the strong and weak signal groups. The nature of SBH data analysis makes it suitable for neural network applications, in which decision-making parameterization is learned by software analysis of data sets with known outcomes. The quality of processing software is measured by its ability to extract all useful information from complex hybridization data sets that contain noise.

Figure 9 An SBH array image containing 55000 cDNA spots. Inset shows enlarged region covering approximately 500 DNA samples. Signal intensity is proportional to the amount of bound DNA, the concentration of labeled probe used, numbers of full match and mismatch binding sites, and probe–DNA hybridization strength, which itself is a function of probe length, sequence, and hybridization conditions.
and error. With proper data analysis, accurate clustering, mapping, and sequencing results are obtained within tolerable error limits. Algorithms for some of these applications are described in section 9.

9 SELECTED STUDIES

In recent years, oligonucleotide hybridization technology has been applied in a variety of important research studies. These include de novo sequencing, gene discovery and fingerprinting, and genetic polymorphism studies. These studies are described in detail below.

9.1 De Novo Sequencing

Drmanac et al. were the first to report successful de novo SBH sequencing. In a blind test, the researchers used both traditional gel methods and SBH to sequence homologous primate T-cell DNA fragments cloned into an 8 kb M13 vector. The similarity of the DNA targets and the occurrence of many single-base mismatches between targets and probes provided a stringent test of the SBH method despite the reduced overall experimental complexity.

In the first stage of this study, one research team sequenced three 2-kb T-cell β loci inserts by traditional sequencing methods. These homologous inserts, derived from human and two rhesus monkey species, were shown to be 92–94% similar in sequence. A second research team used SBH to sequence homologous 116 base pair regions of these clones.

The gel sequencing team constructed a list of 272 octamer probes for determination of the sequences by SBH. The selected probe list contained about twice as many nonmatching as matching probes. The matching probes consisted of all 8-mers with more than three G + C bases or 9-mers with one to two G + C bases that occurred in the 116 base pair DNA segments. To increase the experimental complexity, similar probes corresponding to a fourth primate species (not included as a DNA target) were included in the probe list as well. The SBH research team was informed the list would allow determination of at least one of the sequences and that the other two sequences were similar.

Figure 10 shows representative hybridization images obtained using different 8-mer and 9-mer probes tested against a filter containing 96 DNA samples spotted in duplicate. The filter was prepared directly from M13 phage cultures containing the 116 base pair inserts. Positive and negative DNA controls consisting of M13 DNA were also included, to allow calibration of the hybridization signals for each probe. Pools of sixteen 10- and 11-mer probes containing two degenerate bases as well as the given 8- or 9-mer core were used in these hybridization studies. The longer probes increase hybrid stability and hence signal intensity.

DNA filters were first hybridized with a “mass probe” specific to the M13 vector, to determine the amount of DNA present in each spot. Each filter was then successively hybridized to a series of test probes. The average discrimination value (defined as the average ratio of signals from hybridization with matched and mismatched targets) obtained for probes in this study was over 10. Figure 10 clearly shows the strong signal intensity and hybridization discrimination obtained from probe hybridizations in this study. The DNA sequences of the three unknown targets were precisely determined after hybridization with only 156 of the 272 probes.

Of the 468 probe hybridization scores obtained in this study, 22 positive signals were observed that were inconsistent with the final reconstructed sequences. In 11 of these cases, the positive signals resulted from full-match hybridizations with the M13 vector. Most of the remainder (seven cases) occurred because of the summation of
signals caused by two or more single-mismatch hybrids. In four cases, positive signals resulted from hybridization with a single mismatch target.

Both SBH and traditional gel methods gave identical results for all target DNAs sequenced in this study. Although the number of probes used was greatly reduced relative to the set of all possible octamers, the similarity of the DNA targets and the many single-base mismatches posed technical challenges comparable to those found in a much larger sequencing project.

9.2 Gene Discovery and Gene Expression

Oligonucleotide hybridization has great potential as an investigative tool in gene discovery studies. The ability to simultaneously process thousands of clones in parallel allows researchers to screen large gene libraries in search of rare or tissue-specific genes.

Gene discovery efforts are based on the concept of identifying gene-specific “sequence signatures” for each gene using the hybridization SP (see Figure 1). In gene discovery projects, thousands of cDNAs are spotted to a membrane and then hybridized sequentially to individual probes. Because each n-mer probe binds (on average) once in 4^n bases of target DNA, the set of probes that bind a given cDNA usually provides a unique, sequence-defining “signature” for that gene. Identical or closely related cDNAs can be “clustered” based on their similar signatures.

In an important early demonstration of gene discovery methods, Drmanac et al. screened 73,536 cDNA clones derived from infant brain libraries. Using 200 to 320 oligomer probes (mainly 7-mers) to hybridize these clones, they identified 19,726 distinct genes and estimated that up to 20,000 additional genes are expressed in the infant brain. Clones from both ordinary and normalized gene libraries were used in the infant brain study. cDNA inserts were amplified directly from bacterial cultures in 96-well plates and then pipetted into 864-well plates. Samples from thirty-six 864-well plates were spotted onto a single 16 cm × 24 cm filter using a Beckman Biomek 1000 robot equipped with an 864-pin tool. Negative control spots (without DNA) were arrayed on each membrane to determine background binding. Selected clones of known sequence were used as positive controls.

The probes selected for the infant brain library study were chosen because they occur frequently in coding regions or otherwise help distinguish unrelated clones. Probes were 32P labeled and hybridized under short-wash, low-temperature conditions designed to generate a wide range of signal intensities and to allow maximum discrimination of unrelated clones. Signal intensities were measured for each clone–probe pair using a Molecular Dynamics PhosphorImager, and a raw intensity value calculated using a specialized analysis program.

A number of cDNAs were rejected from the data analysis due to insufficient DNA or problems with spotting. Using minimal acceptable standards for amount of DNA spotted and number of successful probe hybridizations per clone, a set of 57,419 cDNA clones was selected for further analysis. Of these, 38,900 were obtained from the ordinary library and 18,519 from the normalized library.

For each clone selected, the hybridization intensities of all probes tested against it are ranked from 1 to 100 and these rankings are used to calculate similarity values (SIMs) with other clones. The SIM for a pair of clones is defined as follows:

\[ \text{SIM} = \frac{\sum (S_i/L_i)^2}{N} \text{ for } L_i \geq T \]

where \( S_i \) and \( L_i \) are the smaller and the larger of the two rank scores of the \( i \)th probe for a pair of clones, \( T \) is a threshold used to eliminate probes that rank low with both clones, and \( N \) is the number of probes actually used in the pair-wise comparison. Using statistical considerations, a threshold SIM value of 0.57 was calculated to be the optimal level to distinguish clones within a shared cluster from those that are dissimilar. Observed SIM values range from an average of 0.34 for random, unrelated cDNA clones to 0.71 for cDNAs derived from different PCR preparations of a single clone. Sequences that differ randomly at more than 7% of base positions are likely to result in SIM values less than 0.57 and hence would group in different clusters.

Using the clustering criteria described above, the researchers discovered a number of interesting patterns in the ordinary and normalized gene libraries. As expected, the ordinary library contained much larger clusters than the normalized library. The three largest clusters from the ordinary library contained an average of 339 clones each, while the three largest clusters in the normalized library contained much larger clusters than the normalized library. The three largest clusters from the ordinary library contained an average of 339 clones each, while the three largest clusters in the normalized library had an average of 56 members. Using various statistical criteria, the researchers were able to determine that most two-clone clusters represent real groupings rather than random associations. However, false negatives (failure to associate two related clones) were found to occur in about 5% of cases.

ESTs of several clones were compared with GenBank data to determine the likelihood that cluster pairings were inaccurate. In general it was found that clones from a single cluster whose sequences matched GenBank data were either identical or very similar to one another. Even in cases where ESTs from two clones within a single cluster seemed dissimilar the most plausible explanation is that they simply represented nonoverlapping regions of different length clones of a single gene.

The researchers also used a clustering process to examine the expression pattern of mRNAs within the
ordinary brain gene library. Only a few of the 14 010 genes that were expressed in the ordinary (non-normalized) gene library were shown to be responsible for most of the expressed mRNAs within the infant brain. Over 50% of all mRNAs were representatives of the largest 10.8% (1519) of clusters. Nearly 72% of infant brain genes were represented by only a single clone cluster. The average cluster contained 2.4 clones.

In the normalized library, clone abundances of the most commonly expressed genes were typically reduced by 10- to 50-fold relative to the ordinary library. Some genes, however, showed increased expression in the normalized library. Overall, the normalization process reduced the number of clones from the most common gene classes from 29.6% to 5.1% of the total.

One of the most valuable aspects of large-scale fingerprinting projects such as this one is the acquisition of large data sets that allow statistical inference about the population from which they are obtained. Using the number of observed one-, two- and three-clone clusters and assuming an expected binomial distribution, it is possible to predict that a total of at least 40 000 genes are expressed in the infant brain. The current study discovered roughly 19 726 of these, but a much larger clone set would be necessary to capture the complete set of expressed genes. It is predicted that up to 840 000 clones would be necessary to find 99.9% of the genes expressed.

The major advantages of using oligonucleotide hybridization in large gene discovery projects such as the infant brain library study are its ability to:

1. identify and assess genes and cDNA transcript variants that are expressed at low levels;
2. measure differential gene expression between various tissue or cell lines for all genes, without previous knowledge about gene sequence, expression, etc.

The use of very large clone sets greatly enhances the ability to detect rarely expressed cDNAs (due to increased sample sizes), and also improves clustering precision for alternatively spliced messenger variants. Given the low expression of many genes within the human genome and the expected continuum of similar genes within gene families, oligonucleotide technology is likely to be an enormously valuable tool in gene discovery and expression studies.

9.3 Individual Sequencing to Discover Novel Polymorphisms and Mutations

As disease prevention and personalized treatments such as gene therapy become increasingly important medical procedures, there is a growing need for methods that can detect mutations in patient DNA samples. Complete gene sequencing is the best approach to ensure that no mutation will be missed, but gel sequencing methods are slow and costly. On the other hand, SBH is an efficient, cost-effective method of screening large numbers of medically important DNA samples by sequencing for such individual variations.

Drmanac et al. demonstrated the accuracy and speed of using SBH to detect individual mutations by sequencing the medically important p53 gene. In a blind experiment, they used 7-mer probe sets to accurately sequence 12 p53 samples that had a variety of individual mutations, including insertions, deletions, and substitutions. Test samples were generated by in situ mutagenesis of a single p53 clone, with a target mutation rate of one base change per exon. Exons 5–8 and the flanking intron regions were then amplified by PCR to obtain a high concentration of target DNA relative to background genomic DNA.

Amplified DNA was spotted directly to membranes without any further purification, a protocol that could be applied to any DNA sample. Samples were spotted in 8 × 8 replica arrays (each 6 mm × 6 mm) on GeneScreen membranes. Eight such membranes were prepared, containing a total of 3072 replica arrays. A metal grid matching the membrane array pattern was prepared, containing 384 isolated hybridization chambers.

The researchers used two probe sets in the p53 study. One set consisted of all 2186 7-mer probes that complement the reference p53 exon amplicons. The second set of 8192 probes consisted of all 7-mers that contain at least four G + T bases. The G – T-rich probes were chosen because empirical data have shown that they hybridize more efficiently than C – A-rich probes. Using only the G – T-rich probes does not result in loss of sequence information because each probe will bind either one DNA strand or its complement. Probes were 33P-labeled and hybridized to DNA arrays under low-temperature short-wash conditions.

After hybridization and washing, images were scanned using a PhosphorImager scanner (Molecular Dynamics, Sunnyvale, CA) and then analyzed using a special software package that assigns a signal intensity score for each DNA dot. Figure 11(a) shows hybridization images for the target DNA samples analyzed in this experiment. Negative control spots were used to measure background signal intensity. The signal intensities for probes positive to the control (normal) samples were used to quantify the amount of DNA contained in each spot. The adjusted signal intensities were then used to form a sample/control (S/C) ratio for each base consisting of the median S/C values of the 7 or 14 probes that cover that base in sequence. The S/C value quantifies the relative binding strengths of probes for the test and control DNAs at that base position.
Figure 11 Mutation discovery. (a) Probe hybridization images used to detect G-to-C substitution in exon 6 of p53 gene mutants. Results of hybridization experiments involving two sets of seven probes covering this site are shown. Top panel: probes complementary to wild type sequence with base G; bottom panel: probes complementary to mutant sequence containing base C. DNA samples corresponding to exons 5, 6, 7, and 8 are spotted in an 8 × 8 square array. Exon 6 DNA dots are located in the top right quadrant of each square, with normal (wild type) reference DNA in the first row and mutant DNA in the second row. Top panel probes, positive to the reference DNA, show strong hybridization signals with dots 5 through 8 of the first row and negative signals for the mutant sample in dots 5 and 6 of the second row. Bottom panel (mutant) probes show exactly the reverse pattern. The other strong signals visible in various images are two corner markers, additional exon 6 test samples with no mutation, or the remaining three exons. (b) Mutation scanning of p53 gene samples. Median signal ratios of test and control DNA (S/C) for reference positive probes are plotted against base position for two exon 5 samples. For more details see text. Mutated samples contain an insertion of a C at position 122.

The sequencing of gene variants is a two-step process that involves plotting S/C ratios for both probe sets. A plot of S/C values for the probe set positive to the control DNA is called a “mutation scanning graph” and is used to detect mutations in test DNA samples. When test and control DNAs are identical in a given region, S/C ratios are expected to be unity. When a mutation occurs in a test DNA, the S/C ratio for the mutation scanning graph tends to drop dramatically due to failure of wild-type probes to hybridize the test DNA.

Figure 11(b) shows a typical mutation scanning graph for a p53 test sample mutated at base position 122 in exon 5. The two curves shown reflect homozygote and heterozygote mutations in test DNAs. When the mutation occurs in both chromosomes (homozygote) S/C ratios tend to drop to less than 0.5; when a mutation occurs in only one chromosome (heterozygote) S/C ratios typically drop to between 0.5 and 0.8. The clear “opening” in the curve at base position 122 confirms the occurrence of a mutation. Once a mutation has been detected, a sequence determination graph of median S/C ratios from the larger probe set is used to determine the mutated sequence. In this case, probes specific to the mutated test DNA but not the control provide high S/C signals.

A total of 13.2 kb of p53 DNA (12 samples × 1.1 kb each) were sequenced with 100% accuracy in this experiment. The most difficult sequence assignments are in regions that contain single-base repeats of six or more nucleotides. When a mutation occurs in one of these regions, only one or two of the seven overlapped probes are not shared by the two sequence variants. In one such case, a small number of longer (9-mer) probes were used to confirm the sequence. In longer direct repeat regions

a Amplicons corresponding to each of four exons are tested separately.
b The base position of the mutation in the p53 gene sequence is indicated using accession number X54156 from Gene Bank as a reference.
c The exact type of mutation and its heterozygote or homozygote status are also indicated, with “i” indicating an insertion and “d” a deletion.

it may be preferable to use gel sequencing to confirm the final sequence.

An important advantage of SBH is that multiple, independent reads of both DNA strands help ensure accurate, reproducible sequence determination. Five replicate samples of one p53 gene were amplified and sequenced independently to confirm the reproducibility of the SBH process between runs. The coefficient of variation for median S/C values at mutant sites was below 3% for all cases, which is considered well within standards for most clinical diagnostic studies. Overall, the standard deviation of median S/C values in this study was about 6%. It is estimated that such random variation will result in a median S/C value that falls below the 0.8 threshold roughly once in 2500 bases. In the few cases where such false positives occurred the absence of a corresponding peak in the sequence determination graph was used to rule out the possibility of a real sequence change. In conclusion, the SBH method provided 100% accurate sequence determination for over 13 kb of DNA containing a variety of substitution, deletion, and insertion mutants (Table 3).

10 CONCLUSION

The precise instructions for an organism’s development and function are recorded and reproduced in the sequences of genomic DNA or RNA molecules through a self-encoding evolutionary process. This information is expressed in three distinct ways: directly as three-dimensional nucleic acid structures (for example, promoter regions that allow specific interactions with transcription factors) or, by transcription and translation, as RNA or protein molecules. Complex networks of interactions between these three basic types of molecules define spatial/temporal and quantitative aspects of self-control necessary for the organism’s development or for responses to environmental changes. To be able to understand the enormous number of interactions that exist in these networks, we need to collect and analyze extremely large sequence data sets. We have argued, for example, that sequencing every human gene in about 1000 individuals and defining about 1 million functional DNA polymorphisms is of critical importance. We believe that SBH will become the technology of choice in such projects.

SBH is a versatile, cost-effective method for obtaining the accurate DNA sequence information that is needed to fully understand the implications of genetic variation. The oligonucleotide hybridization and SBH methods use either complete or partial sets of DNA oligomers to identify complementary sequences contained within a target DNA. A small set of oligomer probes may be used to identify an unknown DNA by obtaining its “fingerprint” or “sequence signature,” greatly reducing the workload and cost of large-scale sequencing projects by minimizing the number of redundant clones that are sequenced. Larger probe sets may be used to completely sequence a target gene or to detect all mutations relative to a known reference DNA. The multiple overlapping nature of probe sets used in sequencing studies provides high data redundancy and helps ensure accurate sequence information. The use of robotics and microarray technologies allows the processing of hundreds of thousands of probe–DNA hybridization results per day. In its gene discovery program, Hyseq, Inc., routinely fingerprints over a million cDNA clones per month using a single production line. In the more than 10 years since its conception, SBH has become a critical research method, with applications in almost all aspects of genomics. With the explosive growth of genomics research, medical diagnostics, and pharmacogenomics, the coming decades promise even greater developments in SBH technology and its applications.

ACKNOWLEDGMENTS

We thank Radomir Crkvenjakov for analyses, discussions, and critical readings of the manuscript, and Elizabeth Garnett for her excellent organizational assistance throughout this project and for preparation of tables and figures.

Sequencing procedures are aimed at the determination of sequences of monomer units constituting linear biopolymer molecules. In the particular case of nucleic acids the monomer units are DNA or RNA residues. The present article reviews several sequencing strategies: different approaches (random or systematic sequencing) as well as their combinations giving the best results for long-range sequencing applicable to long and unique DNA fragments, including entire genomes, up to the Homo sapiens genome size; massive sequencing of relatively short fragments such as RNAs, complementary DNAs (cDNAs), etc.; and comparative sequencing of related DNA fragments originating from various individuals or different species.

Although particular sequencing approaches may involve different ways of DNA treatment (chemical, enzymatic, or physical), they are all based on the same idea: a labeled molecule is cut to obtain a set of fragments all having one common end, other ends being different owing to the statistical character of the nucleic acid chain cleavage. The fragments obtained are then separated according to their lengths.

The primary structure of nucleic acids is a key not only to physical and chemical properties of the molecules but also to the biological (genetic) information therein, including structures of genes and proteins, the ways of gene regulation and cell response to different signals. This is a great advantage over other physical, chemical, or biological methods of DNA/RNA analysis. However, sequencing in itself is usually insufficient to predict unambiguously the biological properties and functions of the encoded products.

1 INTRODUCTION

The organism stores its genetic information in linear molecules of the genomic DNA and this information can be read using DNA sequencing techniques. The primary structure of any natural DNA molecule harbors not only sequences of proteins and RNAs encoded by genes but also the information on gene regulation. Owing to recent advances in sequencing and cloning techniques, the nucleotide sequences of genes often become available long before the functions of these genes in the organism are established. The possibility to analyze entire genomes of various organisms greatly facilitates the finding and identification of new genes and promotes biological studies.

The Human Genome Project (HGP) was officially started in 1990 to map and sequence the whole human genome and the chromosomes of several model organisms. At present the genomes of several microorganisms and bacteria, as well as some model genomes, are already completely deciphered. HGP is a unique project that is supposed to revolutionize biology and medicine. The high-quality sequence of the human genome will have an unprecedented impact and will always be of great value for basic biology, biomedical research, biotechnology,
and health care. A new era in biology – sequence-based biology – will stimulate the progress in understanding gene–environmental interactions and in the development of highly accurate DNA-based medical diagnostics and therapeutics.

2 BRIEF HISTORY OF NUCLEIC ACID SEQUENCING

The first nucleotide sequence (alanine transport RNA of yeast) was determined in 1965 by Holley et al. using an approach initially developed for proteins and successfully used for insulin sequencing. Improvements of the approach made it possible to sequence RNA genomes, and the first RNA genome of MS-2 phage was deciphered in 1975. The development of DNA sequencing progressed substantially more slowly because DNA molecules are much larger, and at that time no deoxyribonucleases (DNAses) with single-base specificity suitable for enzymatic hydrolysis were known. Study of possible chemical modifications of heterocyclic bases resulted in the chemical cleavage method of Maxam and Gilbert (1977). But only the discovery of restriction endonucleases capable of cutting DNA at specific sites, as well as DNA- and RNA-dependent polymerases, has made a revolutionary breakthrough in DNA sequencing. The development of the primer-extension idea reviewed in detail by Wu has led to the dideoxynucleotide chain-termination method by Sanger et al. who shared the Nobel prize with Gilbert for sequencing. Bacteriophage \( \Phi X \) 174 (5386 bp) was the first sequenced by Sanger et al. After this, a number of whole genomes of several viruses and organelles were determined: among them the genome of bacteriophage \( \lambda \), the 229-kb genome of cytomegalovirus, the 192-kb genome of vaccinia, and others. The whole-genome random sequencing strategy was proposed by Venter et al. and used for sequencing of some microbial genomes. The full-length genomes of Saccharomyces cerevisiae and Escherichia coli were reported in 1996 and 1997, respectively. Currently, active genome sequencing projects are being implemented on insects and more complicated organisms such as Drosophila melanogaster (9% done by the end of 1998), Caenorhabditis elegans (80% completed by the end of 1998), mouse (10 000 sequence-tagged sites (STSs) mapped), and Homo sapiens.

3 SEQUENCING PRINCIPLES AND TECHNOLOGICAL DEVELOPMENTS

All modern sequencing approaches are based on one and the same idea: labeled DNA is treated chemically or enzymatically to obtain a set of DNA fragments all having one common (identical) end, other ends being different owing to the statistical character of the treatment. The fragments obtained can be separated according to their lengths. The methods of DNA treatment are described below.

3.1 Methods Based on Hydrolysis of DNA (RNA) Molecules

3.1.1 Chemical Modifications Followed by Hydrolysis

The idea proposed by Maxam and Gilbert is illustrated in Figure 1. The DNA fragment is end-labeled and modified by a chemical agent specific for a certain

![Figure 1](image-url)
SEQUENCING STRATEGIES AND TACTICS IN DNA AND RNA ANALYSIS

Scheme 1  Biochemistry of chain termination.

heterocyclic base or a definite type of base (listed in Table 1). The extent of modification is chosen so that
finally an average of only one break is introduced in
each polynucleotide chain. After this partial and specific
modification, amine-catalyzed statistical degradation of
the modified chain is performed, and the products of
this degradation are separated in polyacrylamide gels.
By using four different cleavage reactions, the entire
sequence can be read. The Maxam–Gilbert procedure is
complicated and difficult to automate, so its application
to modern large-scale sequencing is limited. However,
it can be used for sequencing of “problem templates”,
which is a common problem in DNA–protein interactions (‘‘footprinting’’)
or DNA structures, and oligonucleotide sequencing. A
similar approach was applied to RNA by Peattie.

3.1.2 Digestion with Specific Ribonucleases:
RNA Sequencing

Radioactively labeled fragments of RNA can be
sequenced using partial splitting by specific ribonucleases
(reviewed by Kuchino and Nishimura). A comprehen-
sive list of the ribonucleases used is given below (see
section 5.2). The application of ribonucleases (RNAses)
is restricted by their rather low specificity. Moreover, the
RNA degradation rates differ depending on the type of
heterocyclic bases.

3.2 Method Based on Specific Termination of Primer
Extension

Another approach called the dideoxynucleotide method
was proposed by Sanger et al. in 1977. It is underlain
by the ability of DNA polymerase to extend a primer
annealed to the template in the presence of four
deoxyribonucleoside triphosphates (dNTPs) – dATP, dCTP,
dGTP, and dTTP – one of which is usually radioactively
labeled to visualize a newly synthesized chain. The
growing chain is terminated by a 2',3'-dideoxyribonucleoside
triphosphate (ddNTP) that blocks the running DNA
synthesis (Scheme 1). In this way the synthesis from a
unique primer in the presence of all four dNTPs and one
ddNTP yields a population of molecules with common
5'-ends but different 3'-ends, depending on the site where
the ddNTP was incorporated. Four separate reactions
with different ddNTPs are performed, the size of each
resulting fragment being determined by the sequence of
the template.

The procedure was initially developed for the large
fragment of Escherichia coli DNA polymerase I
(Klenow fragment) and avian myeloblastosis virus reverse
transcriptase. Ideally, a sequencing enzyme should be
characterized by high processivity and a high rate of
nucleotide incorporation; it should also be free from
exonuclease activity and should not discriminate against
nucleotide analogs. Working in this direction, Tabor and
Richardson introduced a chemically modified deriva-
tive of phage T7 DNA polymerase (known also under the
commercial name of Sequenase), which met all these
requirements. The method is very efficient, presently
allowing up to 800 bp of the sequence to be read in one
run. It became a routine procedure and, being easily
robotized, is now practically the only method used for
large-scale sequencing (see below).

Wide use of polymerase chain reaction (PCR) amplifi-
cation and new thermostable DNA polymerases allowed
the PCR approach and dideoxy sequencing to be com-
bined. These systems provide the option of using either
end-labeled primers or primers with incorporated label
(such as dNTP). The high temperature used for PCR helps
to circumvent the problem of secondary structures and
increases the stringency of primer hybridization. More-
over, the amount of template used for sequencing can be
markedly reduced to as little as 4 × 10^-15 mol.

3.3 Delimiters Approach

This approach combines the features of both the Sanger
and Maxam–Gilbert procedures. It is based on the
incorporation of so-called delimiters in the course of PCR
amplification that further determine the sites of chemical or enzymatic degradation. A version of this method using thiophosphate-modified nucleotides (2'-deoxynucleoside 5'-α-[P-thiol]-triposphates) as delimiters was proposed by Nakamaye et al.\(^{16}\) PCR products in this version are cleaved chemically by 2-iodoethanol or 2,3-epoxy-1-propanol at the sites of thiophosphate incorporation. An essentially analogous but enzymatic approach\(^{17}\) also uses thiophosphate delimiters incorporated into primer-extension products at specific sites subsequently digested by exonuclease III. This approach seemed promising but had a disadvantage of uneven band intensity due to chemical features of thiophosphates. Porter et al.\(^{18}\) used boronophosphates (2'-deoxynucleoside 5'-α-[P-borano]-triposphates) to perform both amplification and direct DNA sequencing of PCR products. The ability of boronophosphates to be incorporated into growing DNA chains during PCR amplification and to block exonuclease activity, combined with their thermostability, provides a tool for direct PCR sequencing, as demonstrated in Figure 2.

Technological developments, mostly aimed at improvement of the chain-termination Sanger sequencing, involve new ways of separating sequencing products, new DNA polymerases, and new nonradioactive labels. Development of more advantageous DNA polymerases through modification of natural enzymes can be illustrated with the following best-known examples: bacteriophage T7 DNA polymerase chemically modified to inactivate 3'-5' exonuclease activity;\(^{15}\) amino acid changes in the active site (phenylalanine into tyrosine) of several DNA polymerase I family members, to increase the rate of incorporation of deoxynucleotides versus deoxynucleotides and to solve the problem of uniform band intensity;\(^{19}\) truncation of the Thermus aquaticus (Taq) polymerase I N-terminus;\(^{20}\) and the substitution of Asn\(^{543}\) for Ser\(^{543}\) in the large fragment of Taq DNA polymerase (Klentaq\(^{16}\) DNA polymerase) to prevent pausing during DNA synthesis within template regions of complex structure.\(^{21}\)

The use of radioactive labels and autoradiographic detection suffers from several limitations. Radioactive isotopes have a short half-life that requires their regular supply, and their storage is potentially hazardous. Moreover, autoradiography is a laborious procedure involving manual manipulations. Great progress was made in sequencing technology in 1987, when radioactive labels were replaced by fluorescent ones that allowed autoradiography to be substituted by laser-induced fluorescence detection, thus making possible the direct reading of electrophoregrams. In 1986 Smith et al.\(^{22}\) reported the first automated DNA sequencer. They used primers labeled with different fluorescent dyes in four sequencing reactions. In one of the other simplest automated sequencers\(^{23}\) the primer was labeled with tetr methylrhodamine iodoacetamide, the reaction mixture was separated into four parts, and sequence identification was similar to the Sanger technique. To avoid primer labeling, Prober et al.\(^{24}\) proposed a four-colored sequencer based on the use of fluorescently labeled deoxynucleotide chain terminators, allowing only one sequencing reaction to be performed instead of four. However, overlapping fluorescent spectra of the dyes used in this approach resulted in generally poor accuracy. Internal labeling with fluorescein–dNTPs was proposed by Voss et al.\(^{25}\) Three automatic sequencers using this labeling and proposed by Smith et al. were commercialized by Applied Biosystems.
DuPont, and Pharmacia, respectively. The development of new fluorescent labels is in progress, including a new class of energy transfer dyes.\textsuperscript{(26,27)}

Clearly being a step forward over manual sequencing, the automated sequencers also have some limitations. Modern sequencing procedures permit up to 600–800-bp-long sequences to be read in one gel. However, electrophoresis in the rather thick slab gels used earlier had to be run at high currents, with accompanying overheating. More recent slab-gel systems are adjusted to thinner gels, which reduces the separation time.\textsuperscript{(28)}

A new invention in this field is electrophoresis in capillary tubes filled with polyacrylamide gel. Efficient cooling of the capillaries allows higher electric fields (up to 400 V cm\textsuperscript{-1} compared to 30 V cm\textsuperscript{-1} in conventional gels) and provides better resolution of separated DNA fragments.\textsuperscript{(29)} The DNA sequencing by capillary electrophoresis is described in detail in the review by Dovichi.\textsuperscript{(30)} Although capillary electrophoresis does not have crucial advantages over ultrathin slab gels, it has some useful practical features, such as easy replacement of separation medium, easy connection to a microtiter plate, and economy in space at high-throughput sequencing. Moreover, low-viscosity polymers used as the separation medium [e.g. non-cross-linked polyacrylamide,\textsuperscript{(30)} polyethylene oxide,\textsuperscript{(31)} or polyethylene glycol\textsuperscript{(32)}] are handy for easy refilling of the capillary tubes.

4 LONG-RANGE GENOMIC DNA SEQUENCING STRATEGY

4.1 Random (Shotgun) Strategy

A random (shotgun) sequencing strategy was first employed by Sanger in the course of bacteriophage \( \lambda \) sequencing in 1982.\textsuperscript{(7)} The strategy was based on sequencing of unselected (random) fragments of DNA and did not need any physical map. The theory of this strategy was put forward by Lander and Waterman,\textsuperscript{(33)} and later was developed further and used by Venter's group to decipher successfully several microbial genomes. A detailed description of the shotgun strategy is given in a review by Fraser and Fleishmann\textsuperscript{(34)} and in their work on sequencing of the \textit{Haemophilus influenzae} genome.\textsuperscript{(10)} The major steps of the strategy are listed in Table 2.

DNA of a genome is sheared, e.g. by extraction with phenol–chloroform, resulting in \(~50\)-kb fragments, followed by sonication or nebulization up to fragment lengths of 1–2 kb. The mixture obtained is blunt-ended by BAL31 nuclease, size-fractionated, and cloned into plasmid (pUC), phagemid (pGEM), or phage (M13) vectors. The use of \textit{E. coli} strains deficient in all re-combinant and restriction functions reduces possible rearrangements during the cloning. A library should not contain overrepresented clones, and it is usually characterized by an average representation of 6- to 8-fold genome coverage. Combining the sequence data obtained

into one contiguous sequence is performed using software that simultaneously clusters and combines fragments of the genome using a best-matched strategy. For instance, well-developed TIGR Assembler software has been used for getting full-length microbial genomes.\textsuperscript{(10)} A step of filling gaps is indispensable because, according to Lander and Waterman,\textsuperscript{(33)} the distribution of the gaps within the genome is random. There are two types of gaps: sequence gaps with templates available; and physical gaps breaking links between contigs. Sequence gaps can be filled by primer walking along the template. Missing templates can be obtained either by PCR amplification using all possible primers designed for the ends of each contig or by construction of libraries with longer inserts (in bacteriophage \(\lambda\) or cosmids) covering these gaps. The full-length sequence obtained is checked for possible rearrangements and sequencing accuracy. The final step is identification and annotation of open reading frames (ORFs) by a set of algorithms such as BLAST or BLAZE.

The shotgun strategy is a well-developed, high-throughput, and cost-saving sequencing approach that does not need an ordered set of cosmids. However, it suffers from high (6–12) redundancy. To lower this value, Hoheisel et al.\textsuperscript{(35)} fine-mapped shotgun templates before sequencing to order clones by hybridization with individual DNA fragments. A random library ordered by hybridization was then used for sequence analysis. Apart from lower redundancy, this preselection can add important structural information (e.g. positions and types of repeats). Radelof et al.\textsuperscript{(36)} proposed the hybridization of short oligonucleotides with high-density clone filter grids and demonstrated a twofold decrease in redundancy.

The shotgun approach also demands additional efforts to close gaps. Repetitive elements widespread over the eukaryotic genomes aggravate the problem of mistaken contigs. This challenge will probably be eliminated by further progress in sequencing technologies.

4.2 Directed Sequencing

The final phase of any large-scale sequencing project includes closure of gaps, sequencing of repetitive motifs, etc. and is implemented by directed sequencing, mainly primer walking. In the primer walking procedure specific primers are generated for the sites close to the 3'-terminus of a known sequence and used for the following elongation steps and sequencing. The steps of primer design and sequencing are repeated until contigs are fused and both strands are sequenced unambiguously. This scheme was proposed by Strauss et al. in 1986\textsuperscript{(47)} and has been used in several genome projects.

The primer walking approach depends on the availability of inexpensive and reliable oligonucleotide primers. There are a lot of primer design computer programs that automatically suggest primers using a set of well-known criteria, such as features of primer–template interactions [e.g. stability of potential binding sites, especially important for sequencing large inserts in phage P1 artificial chromosome (PAC) or BAC vectors], test for self-complementarity and loop formation, stability of the 3’-terminus, and guanine/cytidine content. Several examples of these programs are Oligo,\textsuperscript{(38)} Primo,\textsuperscript{(39)} Primer Master,\textsuperscript{(40)} and PRIDE.\textsuperscript{(41)}

The efficiency of the primer walking in manual sequencing is typically about 80% but under optimized conditions of automated DNA sequencing this value can be as high as 95\%.\textsuperscript{(42)} The primer walking is characterized by low redundancy (2–3 versus 8–10 in the shotgun approach) and low error level (less than 1% per 500 kb). The accuracy can be improved further by simultaneous walking along both strands using two oppositely directed primers, one to obtain new data and the other to confirm already made reads. The primer walking is of great help in the sequencing of repetitive elements and facilitates integration of individual sequences into contigs. All these data were obtained in the course of systematic sequencing of \(S.\ cerevisiae\) chromosome XI in the yeast genome sequencing project.\textsuperscript{(43)}

To avoid the need to synthesize primers for each step of primer walking, Studier\textsuperscript{(44)} proposed sequencing cosmids using libraries of 8-, 9-, and 10-mer oligonucleotide primers. The statistics of priming showed that primer libraries sufficient for determining the sequence of the entire human genome (100 000 cosmids) would be small enough to be prepared and managed. In 1990 Szybalski\textsuperscript{(45)} suggested using a rapid assembly of long specific (modular) primers from short contiguous oligonucleotides taken from a relatively small library containing 4096 hexamers. This idea of a pre-made short oligonucleotide collection was developed further by using oligomers containing 5–7 monomers for constructing modular primers.\textsuperscript{(46–49)} Contiguous oligonucleotide components of the primers being either ligated on the template or used without ligation. A necessary pool of short oligonucleotide components additionally can be reduced, e.g. 1200–1400 hexanucleotides is sufficient for primer walking on natural templates, which was substantiated theoretically\textsuperscript{(50)} and further confirmed\textsuperscript{(51)} practically.

Yet another approach to systematic sequencing – the construction of ordered sets of subclones – was first described in 1980.\textsuperscript{(52)} This idea was developed further in creating new methods to produce nested deletions in vitro. Henikoff\textsuperscript{(53)} proposed the generation of nested deletions starting from any fixed point in a cloned DNA fragment using controlled exonuclease III digestion of the template. The resulting linear nested fragments
had common ends corresponding to the 5'-end of the sequencing primer and could be cloned and used for sequencing. There is also an analogous method in which nested deletions are formed by controlled BAL31 nuclease digestion (see Breault et al.\(^{54}\)). Both procedures are manual and rather laborious; they were widely used before the era of automated sequencing but presently their application is very limited.

An idea to introduce sequencing priming sites throughout the target sequence by bacterial and yeast transposons was elaborated by several research groups. Transposons are inserted into many sites of target DNA cloned in plasmid or phage vectors. The integrated transposons are used to form unique priming sites for the sequencing of adjacent uncharacterized regions. The known DNA tracts within transposons are used as binding sites for sequencing primers. Transpositions are generally made in vivo in bacteria using a donor strain carrying the transposons either within a vector or integrated in the genome. A target of interest is introduced into a transposer host to be hit by transposons. The modified targets are then recovered from the host by genetic selection. To be efficient in sequencing, the transposon technique should meet the following requirements: the transposon should be mobilized easily; selection for transposon insertions into the plasmid and into the target sequence should be efficient, as opposed to the bacterial chromosome; and mapping of the transposition sites should be easy in order to minimize the number of required sequencing reactions. Here are some examples of the transposon systems: \(\gamma\);\(^{35}\) Tn3;\(^{36}\) Tn5;\(^{57,58}\) Tn10;\(^{59}\) AT-2;\(^{60}\) Ty1.\(^{61}\) The transposon sequencing approach was applied successfully to the sequencing of repetitive regions and filling the remaining gaps in the nematode \(C.\) \(e\)legans genome sequencing project.\(^{62}\)

### 4.3 Combination of Random and Directed Sequencing as the Basic Strategy of the Human Genome Project

The HGP was officially started in 1990 as a 15-year collaborative program of mapping and sequencing of the complete set of human chromosomes (3 Gb). The most widely used approaches to human genome sequencing are currently based on preliminary genetic (genes ordered along a chromosome) and physical (overlapped DNA fragments covering a chromosome) mapping of chromosomes. Three clone libraries of different resolution levels were constructed by separating sheared DNA into fragments of different sizes and then inserting them into vectors capable of being propagated in appropriate hosts (Table 3).

The low-resolution physical map in Figure 3 is a set of overlapped YACs containing unique sites amplified by PCR [so-called STSs introduced by Olson et al.\(^{63}\)].

or restriction enzyme recognition sites. Cohen et al.\(^{64}\) described a YAC library of 33 000 clones spanning essentially all human chromosomes. A high-resolution map is made by subcloning YAC inserts into cosmid vectors. Sequencing a cosmid library from both ends provides medium-range linking (about 1 per 10 kb) that spans common repetitive elements. A partially overlapped set of cosmids is then subcloned into M13 vectors and sequenced by a combination of shotgun and primer walking methods.

The accuracy of this approach is high because of high redundancy. However, some limitations still exist: e.g. YAC clones are structurally unstable, which results in rearrangements and deletions; and arrayed repeats present problems for high-resolution mapping.

A novel approach to genomic sequencing that eliminates the stage of prior physical mapping uses BAC clones as a starting point.\(^{65,66}\) The BAC cloning system (Figure 3) was adapted to maintain genomic fragments 300-kb long, the clones being stable even after 100 generations of serial growth.\(^{67}\) The BAC-end sequencing strategy originally proposed to accelerate genome sequencing provides markers every 5 kb throughout the genome. These so-called STCs link all BAC clones to each other and, being combined with the fingerprint of each BAC clone, supply BACs of interest with “seeds”. These “seed” BACs can be sequenced by any method. Venter’s group believes that such an approach might eliminate the problem of gaps in high-resolution physical mapping.

Moreover, Perkin Elmer announced a new, fully automated capillary-based sequencer ABI PRISM 3700 characterized by high throughput (~1000 samples per day with 15 min of hands-on operator time). This allowed Venter’s group to declare the completion of human genome sequencing in the year 2000.
5 SHORT DNA/RNA SEQUENCING APPROACHES

5.1 Complementary DNA Sequencing

Whole-genome sequencing is becoming a routine though laborious procedure, but gene identification and functional analysis of encoded genes remain problematic. From this point of view, cDNA sequencing is one of the main sources of information. Detailed analysis of new methodologies allowing expressed genes to be identified and differences in their expression levels to be quantitated is presented in reviews by Fraser and Fleischmann and Carulli et al.

5.1.1 Expressed Sequence Tags and Serial Analysis of Gene Expression

Expressed sequence tags (ESTs) and serial analysis of gene expression (SAGE) provide a rapid and efficient method of searching for new genes and identification of the coding regions within gene sequences, as well as studying differential gene expression in a variety of normal, developmental, and affected tissues. The EST approach first appeared in the work of Venter’s group on the identification of new human genes expressed in brain, and later was applied successfully to many other tissues (liver, heart, testis, pancreatic islet cells, etc.): a comprehensive list of references is given in a review by Fraser and Fleischmann. The SAGE methodology was developed by Velculescu et al., who analyzed the messenger RNA (mRNA) from human pancreas. The technique allows one to measure the transcript abundance based on the position and content of small sequence tags. Recent examples of SAGE application are the cataloging of ESTs expressed in skeletal muscle, the identification of genes differentially expressed after activation of human arterial endothelial cells, and the analysis of transcripts in non-small cell lung cancer.
The EST and SAGE methodologies complement each other in providing sequence tags for the identification of genes. Development of further modifications of genome-wide gene analysis combining both EST and SAGE is under way. Being widely used, the EST and SAGE methodologies are not free from some limitations. In particular, both of them can be applied only to eukaryotic organisms with polyadenylated mRNAs. Accurate quantitative data of EST analysis depend on large-scale sequencing, which implies the availability of sequencing facilities. The classic SAGE requires relatively high amounts of input RNA, so it is inapplicable when RNA amounts are limited. However, a micro-SAGE modification of the method proposed by Datson et al. works successfully with 500–5000-fold less starting material.

### 5.1.2 Differential Display

The differential display technique first developed by Liang and Pardee is PCR-based and provides data on gene expression. This method uses a set of small random primers to amplify partial cDNAs from subsets of mRNAs. The resulting labeled short sequences are separated in sequencing gels; samples running in parallel show differences in mRNA compositions. The separated labeled tags are isolated from the gel and sequenced. This technique does not require knowledge of the genome context, but it requires extensive follow-up work and is relatively slow.

### 5.1.3 Complementary DNA Microarray Analysis and DNA Chips

These hybridization techniques, as alternatives to direct cDNA sequencing, are fast, accurate, and cheap. Providing that the genome context is known and using the recently developed high-density gridding technique, DNA microarrays can represent every individual ORF from a particular organism and provide a true global pattern of the gene expression under various conditions.

### 5.2 RNA Sequencing

RNA is sequenced according to the general principles given in section 3.

#### 5.2.1 Chemical Degradation

Four different base-specific chemical reactions were proposed for partial and specific digestion of end-labeled RNA. Strand breaks at the sites of the chemical attack generate a nested set of labeled fragments that are resolved by electrophoresis. The modifying reagents are presented in Table 1. Kochetkov et al. introduced an improved uridine-specific modification, later used by Waldmann et al. Solid-phase modifications of the chemical RNA sequencing were described. In this case the reactions are carried out on Whatman DE 81 anion-exchange paper or DEAE-cellulose sheets as support. The base-specific chemical cleavage for RNA sequencing is a powerful technique that is largely insensitive to secondary structure. Unfortunately, the procedure is time-consuming and its application is limited at present.

### 5.2.2 Enzymatic Degradation

Ribonucleases used for RNA sequencing are given in Table 4. All these endonucleases are single-strand-specific. A feature of RNA as compared to DNA is the more complex secondary structure, often hindering enzymatic hydrolysis. Kisselev et al. proposed a complete and selective modification of cytidilic residues by methoxamine–bisulfite mixtures that leads to RNA unfolding. This helps to generate a more uniform set of fragments after RNAse treatment. The C\textsubscript{\textit{modified}}–N bond is easily digested by T2 and A RNAses.

### 5.2.3 Primer Extension

The general principle of specific termination of newly synthesized polynucleotide chains proposed by Sanger is adapted for RNA remains a dominant approach in RNA sequencing. The first chain-terminating RNA sequencing was demonstrated by Kramer and Mills, who used RNA-dependent RNA polymerase (Qβ-replicase) and 3'-deoxyribonucleoside 5'[\textit{α}-\textit{32P}]-triphosphates as specific chain-terminating ribonucleotide analogs. Another RNA polymerase (SP6 polymerase) as well as other terminating ribonucleotide analogs (3'-O-methylribonucleoside 5'-triphosphates) were also tested for sequencing. Nevertheless, RNA-dependent DNA polymerases (reverse transcriptases) introduced by Brownlee and Cartwright are used preferentially (for a review, see Hahn et al.). The procedures for making use of reverse transcriptases from avian myeloblastosis virus and Moloney murine leukemia virus are developed in detail. These methods work equally well with all kinds of labeling, be it labeled dNTPs, labeled primers, or fluorescently labeled ddNTPs. The latter type of labeling minimizes unspecific chain-termination events and is adapted for automated sequencing. Other possible ways to avoid premature chain termination are treatment of RNA templates with methyl mercury and reverse transcription at higher temperatures.

A review of mass spectroscopic RNA sequencing methods can be found in section 5.3.

5.3 New Approaches

5.3.1 Mass Spectrometry

Mass spectrometry (MS) is one of the unconventional approaches ranging between simple replacement of a fluorescent detector in gel electrophoresis with a mass spectrometric detector and attempts to sequence a single DNA molecule in an ion trap. Matrix-assisted laser desorption and ionization (MALDI) was first proposed for the sequencing of large proteins up to 300 000 Da, but in a technically improved form it is now applied also to the sequencing of nucleic acids. The most promising approach is to replace electrophoretic separation of nested DNA (RNA) fragments obtained by the traditional Sanger technique, chemical or enzymatic cleavage with mass spectrometric separation and detection. Cantor et al. suggested a new and potentially high-throughput DNA sequencing approach that uses immobilized duplex probes with five-base-long single-stranded overhangs to bind DNA templates serving as primers for Sanger sequencing. In early studies the sequencing of DNA by MALDI was limited to very short oligonucleotides owing to fragmentation of longer chains during a laser desorption step. Recently introduced matrices have allowed the reliable sequencing of longer DNA fragments of approximately 100–130 nucleotides in length.

Matrix-assisted laser desorption and ionization/mass spectrometry (MALDI/MS) relies on a sample preparation in which the analyzed substance (analyte) is co-crystallized with an excess of a matrix, usually an organic acid. The analyte–matrix mixture is desorbed/ionized by a short laser pulse; the generated ions are all accelerated to the same energy in the electric field and subsequently separated in a field-free drift region according to their mass-to-charge ratio. Sequencing data relying on the absolute molecular mass information rather than on relative gel electrophoretic mobility significantly increase the fidelity of sequencing. Other obvious advantages are fast sequence determination and use of unlabeled primers.

In spite of successful sequencing of rather long DNA stretches (about 500 bp), the main MALDI application is comparative (diagnostic) DNA sequencing and re-sequencing or detection of mutations, because the DNA to be re-sequenced is usually not very large. Unambiguous detection of polymorphic sequences has been demonstrated in both homozygous and heterozygous samples.

5.3.2 Scanning Tunneling Microscopy

Scanning tunneling microscopy (STM) was used to visualize duplex DNA at atomic resolution. Experimental STM profiles showed a double-helical structure, base pairs, atomic-scale substructure, and excellent correlation.
5.3.3 Pyrosequencing

A novel sequencing approach\(^{(107)}\) involves coupled enzymatic reactions to monitor the release of inorganic pyrophosphate (PP\(_i\)) during the DNA polymerase reaction (Figure 4). An oligonucleotide primer is hybridized to a template, and sequencing is carried out by a stepwise elongation of the primer strand upon successive addition of four different dNTPs in the presence of DNA polymerase, ATP sulfurylase, firefly luciferase, and apyrase (nucleotide-degrading enzyme). The synthesis of DNA is accompanied by an immediately monitored release of PP\(_i\) in an amount equivalent to that of the incorporated dNTP. The intensity of light emitted in the luciferase-catalyzed reaction can be measured readily with a suitable light-sensitive device (e.g. a luminometer). dNTPs not incorporated are degraded by apyrase. This technique is advantageous in terms of accuracy, flexibility, parallel processing, and automation. Moreover, it makes the use of labeled primers, labeled nucleotides, and electrophoresis unnecessary. Another important advantage is the absence of the compression effect due to the secondary structure of the template. The problem of determining the number of incorporated nucleotides in homopolymer tracks, which stems from nonlinear light response, still exists but according to the authors can be compensated for by using certain software algorithms.

![Figure 4 Pyrosequencing method. PP\(_i\) = inorganic pyrophosphate; dXTP = one of the four deoxynucleoside-5’-triphosphates. [Reproduced with permission from M. Ronaghi, M. Uhlen, P. Nyren, Science, 281, 363–365 (1998). Copyright 1998 American Association for the Advancement of Science.]](image)

5.3.4 Sequencing by Hybridization

The sequence information is obtained here by the hybridization of small probes to a target to be sequenced. Two formats have been proposed. In format I DNA targets are hybridized to a substrate as a replica array and each replica is hybridized with every possible oligonucleotide probe added in solution. Up to 10,000 clones can be hybridized simultaneously on one membrane. This format was first successfully tested in a blind sequencing of three DNA fragments each of 343 bp in length.\(^{(108)}\) In 1998, Drmanac’s group reported sequencing by hybridization (SBH) of 1.1-kb DNA fragments.\(^{(109)}\) However, in the case of octanucleotide probes as many as 65,000 hybridizations are required, which makes this format too laborious. In an alternative approach (format II) large arrays of oligonucleotides on a solid support are hybridized to a labeled target sequence. Details of format II are given in reviews by Southern\(^{(110)}\) and O’Donnell-Maloney et al.,\(^{(111)}\) where the techniques of oligonucleotide arrays preparation, possible support material (surface-modified glass, polypropylene, glass with small patches of activated polycyramide, etc.), and different schemes of data collection and processing are discussed. All the applications of oligonucleotide arrays are underlain by specific base pairing and include comparing sequences/detecting mutations (see section 6.1) and sequencing per se. The theory of the latter is based on the possibility of distinguishing between perfect and imperfect duplexes and reconstructing the sequence of a target nucleic acid from the corresponding set of oligonucleotides hybridized with it. The maximum length of the analyzed target is roughly equal to the square root of the number of oligonucleotides in the array (e.g. to sequence a 200-bp fragment, an array of 65,536 octanucleotides is needed). The length of oligonucleotides can also be a critical factor. The attempts to use hexanucleotide arrays\(^{(114)}\) were of limited success because short duplexes are stable enough only under nonstringent conditions (at high salt and/or low temperatures), which can cause false hybridization signals or even prevent hybridization owing to internal base pairing in the target. Therefore, the use of longer oligonucleotides is preferable but the arrays become too large for existing production methods. Most of the suggested arrays are prepared from octa- and nanomers. The theory of SBH and the accompanying software is being developed.\(^{(115,116)}\)

There are only a few known examples of successful direct SBH, but a combination of SBH and gel-sequencing techniques is promising for large-scale sequencing.

A major disadvantage of SBH is ambiguous reconstruction of DNA sequences due to the presence of various repeats within long DNA fragments. Mirzabekov et al.\(^{(117)}\) supplemented the SBH procedure with the measurement of distances between certain sites (e.g.
NUCLEIC ACIDS STRUCTURE AND MAPPING

restriction sites or PCR priming sites), which eliminated the problem of repetitive elements.

Another SBH feature is a strong dependence on base composition. An enhanced version of SBH, termed positional sequencing by hybridization (PSBH), was proposed by Broude et al.\textsuperscript{118} It uses immobilized duplex probes with single-stranded 3’ overhangs, which pick their perfectly matched DNA targets out of a mixture of different single-stranded DNAs. Ligation of a single-stranded target hybridized to its complementary counterpart in a duplex probe improves the differentiation of perfectly matched targets from those containing mismatches. The use of PSBH in combination with standard solid-state Sanger sequencing without ligation was demonstrated.\textsuperscript{119} As little as five bases of known terminal sequence is sufficient for priming.

6 COMPARATIVE SEQUENCING

6.1 DNA Chips

Possible applications of SBH include physical mapping of overlapped DNA clones, gene expression monitoring, identification of microorganisms, and thermodynamic analysis of DNA duplexes. Oligonucleotide arrays are characterized by a wide range of comparative (diagnostic) applications, such as screening of sequence polymorphism and detection of mutations, HLA allotyping, genetic identification, and revealing of genetic variations. Several examples are given in the work by Hacia et al.\textsuperscript{120}

6.1.1 Detecting Mutations

High-density arrays have been used to screen 3.4-kb exon 11 of the human breast and ovarian cancer gene (BRCA 1) for all possible heterozygous polymorphisms and mutations. An evolutionary sequence comparison of human BRCA exon 11 and its orthologs in closely related species was done. A 2.3-Mb length of the human genomic DNA was examined by a combination of SBH and gel-based sequencing. Based on SBH pilot genotyping, chips were constructed to characterize human diversity.

6.1.2 Comparative Sequencing

As shown in model experiments, the use of arrays allows one to digitize hybridization patterns and thus to facilitate their comparison.

6.2 Bioinformatics

A scientific field called “bioinformatics” is focusing on the creation of computing systems for collection, refinement, analysis, and storage of information. Two areas of bioinformatics are most pertinent to sequencing:

1. Software that allows full-length sequences to be constructed from sequenced regions. An example is one of the most recent programs described by Parson et al.\textsuperscript{121}

2. Comprehensive analysis and comparison of sequences available from databases. Overview of this application was summarized by Sander et al., who provided a creative computing system.\textsuperscript{122}

Large-scale genome projects generate a rapidly increasing volume of sequence information. By 1999, the genomes of several model organisms had been sequenced, and the HGP is expected to be finished by the year 2001. However, most of the available sequences are functionally uncharacterized. The research in bioinformatics results in the development of methods for computational characterization of these sequences, and the number of computer programs specialized for various analytical tasks is growing rapidly. The most improved packages of information and software are distributed through web sites of the largest genome centers: Sanger Center, European Bioinformatics Institute (EBI), Centre National de la Recherche Scientifique (CNRS), Max-Plank-Institute in Europe; Washington University, National Center for Biotechnology Information (NCBI) and other institutions in the USA.

We use delta ribozymes as a model in illustrating the various steps involved in the structural analysis of ribozymes. Delta ribozymes were originally identified as a self-cleaving motif located on the single-stranded RNA genome of hepatitis delta virus (HDV). The methodologies are presented in the order of their requirement for determination of the structure/function relationship of a ribozyme, beginning with the preparation of the RNA molecules required for the studies. Primary structural information is needed in order to identify potential ribozymes, then secondary and tertiary structural information is required for ribozyme characterization. The manuscript was written to guide an investigator from the initial observation of RNA catalytic activity (a ribozyme discovery) to the deduction of a structural model of the ribozyme.

1 INTRODUCTION

Ribozymes are a family of RNA molecules which possess various catalytic capabilities.1–3 The best known ribozymes are the endoribonucleases which are capable of cleaving RNA molecules at specific sequences. This group of ribozymes has tremendous potential for the development of a novel approach for the selective inactivation of specific RNA molecules, including both those derived from pathogenic viruses and those associated with inherited diseases. The underlying theory of this inactivation is that the mRNA encoding a harmful protein would be intercepted and destroyed by the ribozymes before that mRNA is translated. In order to be able to fully exploit the potential of a ribozyme, it is crucial to have a complete understanding of the molecular mechanism of the ribozyme reaction. It has long been known that modification of RNA (ribozyme) structure often results in the alteration of its catalytic properties.

The various methodologies described in this chapter are presented in the order of their requirement for determination of the structure/function relationship of a ribozyme, beginning with the preparation of the RNA molecules required for the studies. Primary structural information is needed in order to identify potential ribozymes, then secondary and tertiary structural information is required for ribozyme characterization. The procedures described below are written so as to guide an investigator from the initial observation of RNA catalytic activity (a ribozyme discovery) to the deduction of a structural model of the ribozyme.

We use delta ribozymes as a model in illustrating the various steps involved in the structural analysis of ribozymes. Delta ribozymes were originally identified as a self-cleaving motif located on the single-stranded RNA genome of HDV.4 The HDV genome is circular and replicates through a rolling circle mechanism involving only RNA intermediates.5 Replication is initiated by the binding of the host RNA polymerase II to the parental RNA and results in the synthesis of a complementary multimeric copy of the HDV genome (Figure 1). The monomeric HDV genome is then released from this multimer by the catalytic activity of self-cleaving motif. This intramolecular cleavage is an RNA autocatalytic reaction. The RNA sequence responsible for the cleavage is known as the delta-cleaving RNA motif, or as the cis-acting ribozyme (Figure 1b). Based on subsequent
Figure 1 The discovery and development of delta ribozyme from HDV. (a) The single-stranded RNA genome of HDV is produced in a multimeric unit. Its self-cleaving motif is responsible for the release of multiple monomeric copies of the HDV genome, which are then re-circularized. (b) The delta-cleaving motif was subsequently identified. (c) From secondary structural analysis, a trans-acting delta ribozyme was derived by separating the junction between the P1 and P2 stems. Secondary structural information obtained by various investigators, this motif has been modified into an intermolecular system (Figure 1c). This so called a trans-acting ribozyme system contains both a substrate molecule and an enzyme molecule.

2 HISTORY

RNA catalysis was first identified in the RNA components of both the group I intron by Cech and RNaseP by Altman in the early 1980s. These discoveries marked the first examples of enzymatic catalysis in the absence of any protein. These catalytically active ribonucleic acids were named ribozymes (RNA enzymes). During the past two decades several ribozymes have been identified that possess various catalytic capabilities which enable them to modify the phosphodiester bonds of their substrates.

3 SYNTHESIS OF RNA FOR RIBOZYME STUDIES

Ribozymes and their substrates can be produced either by in vitro transcription, or by chemical synthesis. The basic requirements and protocols for these two methods are described below.

3.1 In Vitro Transcription

This protocol makes use of enzymatic reactions catalyzed by purified bacteriophage T7 RNA polymerase, which uses DNA as a template. It has been demonstrated that the sequence immediately downstream of the T7 RNA promoter can affect the yield of transcript, and that the initiating nucleotides CCC or CCU give the best yield. Large RNAs are routinely generated by this method. The model substrate of delta ribozyme, an oligomer 11 nt long, is also produced by this method (Figure 2a). Due to the propensity of T7 RNA polymerase to add one or two uncoded nucleotides to the 3'-end of the resultant transcripts, the subsequent purification and verification of both the length and the sequence of the transcripts is required (section 5.2). The main limitation of this method is that it cannot be used when specific modifications are required.

3.1.1 Oligonucleotide Templates

A pair of synthetic DNA oligonucleotide templates can be designed so that one contains the complementary sequences of the T7 RNA promoter and the sequence coding for ribozyme or substrate, while the other contains the sequence of the T7 RNA promoter. Prior to the preparation of an in vitro transcription reaction mixture, the two oligonucleotides (500 pmol each) are mixed in diethylene pyrocarbonate (DEPC)-treated water (20 µL) containing 10 mM Tris(hydroxymethyl)aminomethane (Tris)-HCl pH 7.5, 10 mM MgCl₂ and 50 mM KCl, heated at 95°C for 5 min and allowed to cool slowly to 37°C. The partial duplexes formed then serve as templates for RNA synthesis by T7 RNA polymerase (Figure 2a).

3.1.2 Cloned Templates

The DNA template of delta ribozyme was cloned into the plasmid pUC19 using recombinant DNA techniques (section 4.2). The resultant recombinant plasmid containing the ribozyme sequence is then digested so as to either linearize or release the delta ribozyme insert. T7 RNA polymerase will use the resultant DNA duplex as a template and produce transcripts extending until the end of the duplex, so called run-off transcription reactions (Figure 2b).

3.1.2.1 Materials and Methods

Mix, in a final volume of 100 µL:

DNA template either as a partial duplex (500 pmol) or as a digested cloned template (5 µg)
Figure 2 DNA templates for in vitro transcription reactions catalyzed by bacteriophage T7 RNA polymerase. (a) The partial duplex formed by two oligonucleotides. The substrate (11 nt) of delta ribozyme is illustrated. (b) The double-stranded DNA. The plasmid pUC19 harboring the sequence of trans acting delta ribozyme is digested with either SmaI or HindIII and the resulting linear DNA is used as a template. RNA and DNA molecules are identified in brackets.

Purified T7 RNA polymerase (2 µg µL⁻¹) 2 µL

Incubate at 37 °C for 2–4 h. Add 5 µL RQ1 RNase-free DNase (1 unit µL⁻¹, Promega) to eliminate the DNA template, then extract twice with buffered phenol. Add 0.1 volume of 3 M sodium acetate pH 5.2 and 2 volume of ethanol to the aqueous phase. Chill for 15 min at −80 °C and centrifuge at 4 °C for 15 min in a microfuge. Discard the supernatant then add an equal volume of 70% ethanol and repeat the centrifugation step. Dissolve the pellet in 20 µL of DEPC-treated water and add 10 µL of 5× gel loading buffer (95% formamide, 10 mM ethylenediaminetetraacetic acid (EDTA), 0.05% bromophenol blue and 0.05% xylene cyanol). The mixtures are fractionated by denaturing 20% polyacrylamide gel electrophoresis (PAGE, 19:1 ratio of acrylamide to bisacrylamide) containing 45 mM Tris-borate pH 7.5, 7 M urea and 1 mM EDTA. The reaction products are visualized by ultraviolet (UV) shadowing, and the bands corresponding to the correct sizes of the ribozymes and substrates cut out, and the transcripts eluted overnight at 4 °C in a solution (200 µL) containing 0.1% SDS and 0.5 M ammonium acetate. The transcripts are then precipitated by the addition of 0.1 volume of 3 M sodium acetate pH 5.2 and 2.2 volume of ethanol. Transcript yield is determined by spectrophotometry at 260 nm. The sequence and size of the RNA products are then verified by RNase digestion (section 5.2).
3.2 Chemical Synthesis

RNA molecules can be chemically synthesized in the same fashion as DNA molecules from 3’ to 5’ by taking the advantage of the high chemical reactivity of the 5’-hydroxyl group. It has been reported that the enzymatic activity of the resultant RNA is equivalent to that of RNA derived by transcription methods. Most importantly, chemical synthesis allows the introduction of single-atom substitutions at specific positions in the RNA molecules. There are three major targets for modification in RNAs: the exocyclic base, the sugar, and the internucleotide phosphodiester linkage (Scheme 1).

Presently the cost of production is still prohibitive, especially when large RNA molecules are required. An improved method using the solid-phase chemistry is capable of production in the 200 μmol range; however the chemical synthesis of RNAs longer than 45 nt is not advised when 2′-O-t-butyldimethylsilyl-5′-O-DMT-ribonucleosides (tBDMS-amidites) are used, and of not more than 90 nt when 2′-O-trisopropylsilyl-oxy-methyl-ribonucleosides (TOM-amidites) are used. In some cases where longer RNA molecules are required, the investigator might combine T7 transcription and chemical synthesis (section 3.3) in order to produce the desired RNA.

An automated DNA/RNA synthesizer (for example, ABI Model 392 or 394 from Applied Biosystem, Foster City, CA) and high-performance liquid chromatography (HPLC) system are required for the synthesis of RNA oligonucleotides using tBDMS-amidites phosphoramidites or TOM-amidites, in addition to nucleoside-functionalized CPG or polystyrene supports (A, G, C, U). Due to the special amidites and depurination reagents currently available, various modifications can be incorporated into the synthesized RNA. For example, inosine can be introduced at selective bases, 2′-deoxy or 2′-O-methyl RNA can be substituted for the 2′-OH of the ribose residue. The internucleotide phosphodiester bonds can be replaced by phosphothioate or phosphonate linkages. Moreover, other modifications, such as biotinylated RNA and halogenated deoxy and ribonucleotide incorporation, aimed at facilitating the downstream use of the resulting RNAs can also be incorporated.

Due to the high cost of equipment and materials in general, investigators are advised to order custom-made RNA oligonucleotides from facilities such as Keck Oligonucleotide Synthesis Facility (Yale University, CT), and Xeragon AG (Zurich, Switzerland). Following their synthesis RNA oligonucleotides are subjected to depurination and desalting steps analogous to those for synthetic DNA oligonucleotides. The depurination removes protecting groups from 2′-hydroxyl of the ribose residue using either TBAF or Et3N(HF)3 according to the manufacturer’s instruction, the subsequent desalting step removes inorganic salts, trace organic compounds, low-molecular-weight impurities and short failure sequences. The latter step can be performed using size-exclusion chromatographic columns such as G-25 Sephadex or reverse phase HPLC. However, gel electrophoresis is the method of choice for removal of failure sequences. The sequence and size of the RNA products are verified by RNase digestion (section 5.2).

3.3 Combination Method

Both enzymatic and chemical techniques can be combined in order to obtain target RNA molecules with site-specific modifications at affordable prices. For example, target RNA molecules with a specific phosphothioate linkage isomer can be generated by enzymatic ligation of two individual RNAs, one of which is a chemically synthesized RNA containing a phosphothioate linkage at the desired position. The resultant Sp and Rp isomers are then separated by HPLC. The desired RNA isomer is then joined to the other RNA by T4 RNA ligase. For more examples and details on using a combination of
chemically and enzymatically methods to generate the RNAs of interest, see Vinyak et al.\(^{(14)}\)

**4 PRIMARY STRUCTURAL INFORMATION**

The observation of self-cleaving RNA molecules naturally lead to experiments aimed at identifying the responsible element whether its sequence or surroundings causes the cleavage. In the case of delta ribozymes, a linear dimer of the HDV genome was reported to be initially processed into a monomeric RNA when the responsible cDNA was transfected into a monkey kidney cell line.\(^{(4)}\) These findings suggested that either HDV RNA has an unusual secondary structure that allows a specific attack by a cellular RNase, or that the HDV RNA has a specific self-cleaving activity. The self-cleaving motif of HDV was mapped on both strands of the HDV genome in order to locate the cleavage position.\(^{(6)}\) The steps required for this identification are described below.

**4.1 Sequence Mapping and Self-cleaving Activity**

In general, cDNA coding for the RNA molecules of interest is generated and cloned into a plasmid for identification using standard recombinant DNA techniques. Exonuclease III, a 3' to 5' exonuclease specific for double-stranded DNA carrying either a blunt end, a 5'-overhang, or nick, is commonly used for the construction of unidirectional nested deletion sets from the plasmids. The nested deletion clones can be generated from either end using an appropriate restriction endonuclease that leaves either a blunt end or 5'-overhang to linearize the DNA, followed by exonuclease III treatment. The sequence of each of the resulting deletions is determined by dideoxynucleotide chain-termination sequencing.\(^{(13)}\)

RNA transcripts are then produced by in vitro transcription reactions in the presence of 0.05 mCi [\(\alpha\)-\(^{32}\)P]GTP, and are purified and subjected to various buffered conditions so as to identify the responsible element. To prove that the self-cleaving activity is solely the result of the RNA transcripts, and not due to RNase or proteins present in the in vitro transcription reaction or cell extracts, the purified primary transcripts are incubated in 50 mM Tris-HCl, pH 8.0 and 10 mM MgCl\(_2\) (standard conditions for many ribozyme cleavage assays, including delta ribozymes).\(^{(6,18)}\) The newly formed products are resolved on denaturing polyacrylamide gels, and are visualized by exposure of the gels to either X-ray films or phosphorImaging screens.

**Figure 3** Cloning of the trans-acting delta ribozyme. Four overlapping oligonucleotides were designed so that they encode the entire sequence of trans-acting delta ribozyme. Following annealing of these four oligonucleotides, the resulting fragment was cloned into PstI/HindIII-digested pUC19. The resultant clone was verified by dideoxynucleotide sequencing. The restriction endonuclease sites are identified on the double-stranded DNA.
To characterize the biochemical properties of the self-cleaving motif, the cleavage efficiency is determined in various buffer systems (pH 5.0–9.0) containing either monovalent (Na\(^+\), K\(^+\) or NH\(_4^+\)) or divalent ions (Mg\(^{2+}\), Ca\(^{2+}\) or Mn\(^{2+}\)). The delta ribozyme self-cleaving motif located on the HDV genome was found to be able to use either Mg\(^{2+}\) or Ca\(^{2+}\) as a cofactor for efficient cleavage in Tris-HCl pH 5.0–8.0.\(^6\) The cleavage products were identified as a 3’ fragment with 5’-hydroxyl end, and a 5’ fragment with 2’,3’-cyclic phosphate terminus similar to the products of other ribozyme cleavage reactions.

4.2 Construction of Ribozymes and Their Variants

In order to explore enzymatic properties of a ribozyme, cDNA clones coding for the ribozymes are constructed using recombinant DNA techniques. From the primary structural information (i.e. the sequence and the cleavage site), deoxyoligonucleotides can be designed and synthesized for cloning purposes. The delta ribozymes used in our studies were initially constructed using four overlapping oligonucleotides (Figure 3). Several restriction sites were included in order to facilitate the creation of variant ribozymes. For example, ribozyme mutants carrying a single mutation in the P1 stem can be produced by digestion of the plasmid carrying the ribozyme with the restriction endonucleases, RsrII and SphI. Subsequent ligation of this predigested plasmid to new oligonucleotides having the altered sequence flanked by RsrII and SphI sites led to the production of the ribozyme variant.\(^{19}\)

5 SECONDARY STRUCTURE ANALYSIS

Secondary structural information of RNA molecules is generally considered to be a simplification of what is in fact a three-dimensional complex. RNA secondary structure is predicted using either computer-aided alignment, or experimental data. Both approaches suggest putative base pairs in the three-dimensional structure of the RNA molecule.

5.1 Computer-aided Prediction

RNA secondary structure elucidation is similar to an alignment of protein or nucleic acid sequences, except that the RNA sequence folds back on to itself rather than on to identical or similar bases.\(^{20}\) The complementary bases, G–C and A–U, form stable base pairs through hydrogen bonds between donor and acceptor sites on the bases, and are known as Watson–Crick base pairs. In addition, the weaker G–U wobble pair can be formed in a skewed fashion. These three types of base pairs are called canonical base pairs. Other base pairs (i.e. G–G or C–C) are called noncanonical base pairs.\(^{21}\) The prediction of secondary structure can be made either from a single RNA sequence by minimizing the free energy of folding, or from a common folding pattern observed for a family of aligned, homologous RNAs. To calculate the free energy of RNA folding, arbitrary energy profiles are assigned to each individual base pair type and motif.\(^{22}\) For the past decade, the formulae defined by Turner and his co-investigators have been widely used to define the free energy of stacking of canonical base pairs, hairpin loops, and both interior and bulge loops.\(^{20,22}\)

In general, the secondary structural information obtained using aligned RNA sequences is very valuable because the RNA structure is considered to be conserved to a greater degree than the sequence is. Over a period of sequence drift, the structural similarity might remain essentially the same through the phenomenon known as compensatory base changes, which conserve the base pairs,\(^{22}\) as is observed in the structures of tRNAs or 5S RNA.

5.2 Nuclease Mapping or Enzymatic RNA Sequencing

Enzymatic RNA sequencing is generally used in both the mapping of RNA secondary structures and in the determination of RNA length. This method takes advantage of the cleavage specificity of a variety of ribonucleases and nucleases (Table 1) that are incubated with the substrate RNA in separate reactions. The reaction mixtures are then fractionated by denaturing gel electrophoresis. The resulting bands are compared to an RNA ladder generated from the same RNA. To determine the length of the RNA, several nucleases can be used (Table 1).

| Table 1 Ribonucleases and nucleases that are commercially available, and are commonly used, are listed with their optimal buffer\(^{25}\) |
|------------------------|--------------------------|------------------|
| Nucleases | Cleavage | Buffers (5×) |
| CV or VI | Prefers double-stranded RNA | 125 mM Tris-HCl, pH 7.2 |
| Phy M | Ap↓N and Up↓N | 250 mM sodium citrate, pH 5.0 |
| S1 | Single-stranded nucleic acid | 200 mM sodium acetate, pH 4.5, 1 M NaCl, 50 mM ZnSO\(_4\) |
| T1 | Single-stranded RNA and Gp↓N | 250 mM sodium citrate, pH 5.0 |
| T2 | Prefers single-stranded RNA and Ap↓N | 250 mM sodium acetate, pH 5.0 |
| U2 | Single-stranded RNA and Ap↓N | 250 mM Tris-HCl, pH 7.5 |

250 mM sodium citrate, pH 4.5
5.2.1 Materials and Methods

5.2.1.1 5’-Dephosphorylation of RNAs Mix, in total volume of 10 µL:

- RNA purified from in vitro transcription reaction (10 pmol µL⁻¹) 2 µL
- Calf intestine alkaline phosphatase (Pharmacia) 0.2 unit
- 1 M Tris-HCl, pH 8.0 5 µL
- RNAGuard® RNase inhibitor (Pharmacia) 10 units
- DEPC-treated water

Incubate at 37 °C for 30 min. Extract twice with buffered phenol. Collect the aqueous phase, add 0.1 volume of 3 M sodium acetate pH 5.2 and 2 volume of ethanol. Chill the mixture for 15 min at −80 °C. Centrifuge at 4 °C for 15 min in a microfuge, add an equal volume of 70% ethanol and repeat the centrifugation step. Dissolve the pellet in 20 µL of DEPC-treated water to obtain 1 pmol µL⁻¹ of dephosphorylated RNA.

5.2.1.2 5’-End-labeling of Transcripts Mix, in total of 10 µL:

- Dephosphorylated RNA (1 pmol µL⁻¹) 2 µL
- 10 × T4 polynucleotide kinase buffer (USB) 1 µL
- RNAGuard® RNase inhibitor (Pharmacia) 10 units
- γ⁻³²P ATP (Amersham, 10 µCi µL⁻¹) 3.2 pmol
- T4 polynucleotide kinase (USB) 3 units
- DEPC-treated water

Incubate at 37 °C for 30 min. Add 5 µL of loading buffer (95% formamide, 0.05% bromophenol blue and 0.05% xylene cyanol) and fractionate on a denaturing PAGE. The radioactively labeled RNA band is cut out following exposure of the gel to an X-ray film. The 5’-end-labeled RNA is eluted overnight at 4 °C in a solution (200 µL) containing 0.01% SDS and 0.5 M ammonium acetate.

5.2.1.3 Alkaline Hydrolysis Generation of an RNA Ladder Mix, in total of 5 µL, 5’-end-labeled RNA (50 000 cpm µL⁻¹) in solution containing 50 mM NaHCO₃ and 5 mM EDTA. Incubate at 95 °C for 5 min. Add 5 µL of loading buffer (95% formamide, 0.05% bromophenol blue and 0.05% xylene cyanol) and fractionate on a denaturing PAGE gel.

5.2.1.4 Nuclease Assay The specific cleavage by nuclease at the ribose-phosphate backbone are carried out using various buffering conditions as listed in Table 1. Frequently MgCl₂ or EDTA is also added in order to obtain conditions corresponding to either native or partially denatured folding. Note that the addition of heavy metal ions should be omitted in assays using RNase T2. Moreover, the optimal time required for the mapping is determined depending on the efficiency of each nuclease. The cleavage reaction mixtures are fractionated on denaturing PAGE gels along with the corresponding RNA ladder.

5.3 Chemical Interference

Chemical reagents interact with the heterocyclic bases, the phosphodiester bonds and the ribose moieties resulting in a modified structure (Table 2). The modified residues are detected by primer extension, except when using Fe (II)-EDTA and imidazoles where primer extension is not required in order to resolve the reaction products. Fe (II)-EDTA generates hydroxyl radicals which nonspecifically interact with nucleic acids. Consequently Fe (II)-EDTA is often used for elucidation of the surface residues of an RNA molecule. These interactions occur at the heterocyclic bases and ribose residues, the latter of which results in strand breaks which are detected following gel fractionation. Imidazole and its conjugates rapidly cleave the phosphodiester bonds located in single-stranded regions whereas those located in double-stranded regions are cleaved much more slowly. For delta ribozymes, several research groups have used RNase mapping, chemical interference, and UV-cross-linking procedures to determine delta ribozyme structures. Three versions of the secondary structure are illustrated in Figure 4. The differences result from the different assay conditions used and from the analysis of the mixed population of delta ribozymes present in aqueous solution.

6 NATIVE OR TERTIARY STRUCTURE ANALYSIS

Using both intramolecular and intermolecular (i.e., with surrounding molecules) interactions, ribozymes adopt their native or tertiary structures and thereby gain their catalytic activity. The surrounding molecules used in the intermolecular interaction are metal ions, proteins and water. Over the last few years there has been considerable progress in our understanding of the kinetics of RNA folding and cleavage due to simultaneous advances in both experimental and theoretical methods. Ribonuclease mapping, chemical interference and mutational analyses have been used to define the possible conformations of various RNA molecules. Most significantly, advanced techniques of crystallography, X-ray diffraction and NMR have determined precisely several RNA structures. Currently, the relationship between structure and function has been most thoroughly studied for the group I intron-derived ribozyme. Several of the approaches used in the study of this large ribozyme have also been applied to smaller ribozymes, the best studied of which are the hammerhead ribozymes. However, in some cases structural information from different methods resulted in discrepancies in the proposed structure–function relationship due to the heterogenous population of ribozyme present in aqueous solution. Kinetic characterization has been used widely in the survey of native structural analysis as it relates to enzymatic activity.

6.1 Cleavage Assay

A cleavage assay is the primary method of demonstrating that a ribozyme has adopted its native structure. Like protein enzymes, cleavage assays can be carried out in buffered solution in the presence of trace amounts of radioactive labeled substrate. The radioactive RNA molecules are either the cis- ribozyme (RNA carrying a self-cleaving motif), or the substrate for a trans- ribozyme. The cleavage reactions catalyzed by both cis- and trans- Rz require metal ions as cofactors (i.e. MgCl2, CaCl2 and MnCl2). Denaturing agents such as formamide and urea are sometimes included in the reaction mixture in order to disturb any misfolded molecules and thereby enhance the refolding of the ribozyme–substrate complexes.

6.1.1 Materials and Methods

Mix, in total of 20µL, either radioactively labeled cis-acting ribozyme or radioactively labeled substrate of trans-acting ribozyme (ca. 50,000 cpm) in buffered solution containing 50mM Tris-HCl, pH 7.5–8.0, and 5–50 mM MgCl2. In the cases of trans-acting ribozyme, an approximate amount of ribozyme is added. Incubate the reaction for the time required (i.e. 10–30 min). Stop the reaction by adding 5µL of loading buffer.
addition of MgCl₂ to 10 mM final concentration. The initiation of the reaction. Cleavage is initiated by the reaction catalyzed by delta ribozyme. Trace amounts of substrate (final concentration < 1 nM) are cleaved by various ribozyme concentrations (5–500 nM), and the fraction cleaved is determined. The rate of cleavage \( k_{\text{obs}} \) is obtained from the fitting of the data to the equation \( A_t = A_\infty (1 - e^{-kt}) \), where \( A_t \) is the percentage of cleavage at time \( t \), \( A_\infty \) is the maximum percent cleavage (or the end-point of cleavage), and \( k \) is the rate constant \( k_{\text{obs}} \). Each rate constant should be calculated from at least two measurements. The values of \( k_{\text{obs}} \) obtained are then plotted as a function of ribozyme concentration in order to determine the other kinetic parameters: \( k_{\text{cat}}, M \) and \( k_{\text{cat}}/M \).

6.3 Kinetic Determination

Time course experiments are performed at various substrate and ribozyme concentrations in order to determine kinetic parameters, such as a maximum rate of cleavage and substrate association constant.

6.3.1 Single Turnover Conditions

Various amounts of ribozyme are mixed with trace amounts of substrate (final concentration < 1 nM) in a 18-µL reaction mixture containing 50 mM Tris-HCl pH 7.5, and are then subjected to denaturation by heating at 95°C for 2 min. The mixtures are quickly placed on ice for 2 min and equilibrated to 37°C for 5 min prior to initiation of the reaction. Cleavage is initiated by the addition of MgCl₂ to 10 mM final concentration. The cleavage reactions are incubated at 37°C, and followed for 3.5 h or until the end-point of cleavage is reached. The samples are quenched by the addition of 5 µL stop solution (95% formamide, 10 mM EDTA, 0.05% bromophenol blue and 0.05% xylene cyanol), and are analyzed by 20% PAGE as described above. Both the substrate (11 nt) and the reaction product (4 nt) bands are detected using a molecular dynamic radioanalytic scanner after exposition of the gels to a phosphorImaging™ screen (Figure 4a).

6.3.1.1 Measurement of Pseudo-first-order Rate Constant \( (k_{\text{cat}}, K_M \) and \( k_{\text{cat}}/K_M) \)

Kinetic analyses are performed under single turnover conditions as described by Hertel et al. (28) with some modifications for delta ribozyme. Trace amounts of end-labeled substrate (<1 nM) are cleaved by various ribozyme concentrations (5–500 nM), and the fraction cleaved is determined. The rate of cleavage \( k_{\text{obs}} \) is obtained from the fitting of the data to the equation \( A_t = A_\infty (1 - e^{-kt}) \), where \( A_t \) is the percentage of cleavage at time \( t \), \( A_\infty \) is the maximum percent cleavage (or the end-point of cleavage), and \( k \) is the rate constant \( k_{\text{obs}} \). Each rate constant should be calculated from at least two measurements. The values of \( k_{\text{obs}} \) obtained are then plotted as a function of ribozyme concentration in order to determine the other kinetic parameters: \( k_{\text{cat}}, M \) and \( k_{\text{cat}}/M \).

6.3.2 Multiple Turnover Conditions

Trace amounts of labeled substrate are mixed with unlabeled substrate in order to obtain various substrate final concentrations. Fixed amounts of ribozyme (50 nM) are then added to the substrate mixtures in an 18-µL reaction mixture containing 50 mM Tris-HCl pH 7.5, and then subjected to denaturation by heating at 95°C for 2 min. Again the mixtures are quickly placed on ice for 2 min and equilibrated to 37°C for 5 min prior to the initiation of the reaction. Cleavage is again initiated by the addition of MgCl₂ to 10 mM.

6.3.3 Inhibition Analysis

The inhibitory effects of the substrate and the product can be kinetically tested under both single- and multiple-turnover conditions.

6.3.3.1 Single Turnover Conditions

Conditions similar to those described above can be used with various amounts of potential inhibitors (either substrate, product or oligonucleotide). The reactions are initiated by mixing inhibitors (0.5–20 µM) with substrate (1 nM) prior to addition of the ribozyme (50 nM) in 20 µL enzyme assay buffer (50 mM Tris-HCl pH 8.0, 10 mM MgCl₂). Aliquots (2 µl) are withdrawn at various intervals during the 40-min incubation period, and are quenched by the addition of ice-cold stop solution (6 µL). The samples are fractionated on 10% denaturing PAGE gels, and the reaction products are quantified following exposure to phosphorImaging™ screens. Control reactions are carried out in the absence
of inhibitor. To evaluate the effect of an inhibitor on the intrinsic rate of delta ribozyme cleavage, the data are analyzed as described by Clouet-d’Orval et al.\(^\text{29}\) in order to determine the fraction of inhibition (\(I\)) at each inhibitor concentration. Equation (1) is used:

\[
I = 1 - \left( \frac{k_{\text{attack}}}{k_2} \right)
\]

(1)

where \(k_{\text{attack}}\) and \(k_2\) are the rates of cleavage in the presence and absence of the inhibitor, respectively. The values of \(k_2\) are obtained from fitting the experimental data to the pseudo-first-order rate equation (Equation 2):

\[
A_t = A_\infty (1 - e^{-kt})
\]

(2)

where \(A_t\) is the percentage of product formed at time \(t\), and \(A_\infty\) is the maximum amount of product formed. The fraction of inhibition (\(I\)) is plotted versus inhibitor concentration, and the data fitted to a hyperbolic equation in order to obtain \(N_t\), the inhibitor concentration needed to reduce the rate of cleavage by one-half.

6.3.3.2 Multiple-turnover or Steady-state Conditions
Various concentrations of substrate are mixed with trace amounts of end-labeled substrate (<1 nM) so that final concentration is between 75 and 500 nM in the reaction mixtures. The reaction mixtures contain substrate, ribozyme (50 nM), and inhibitor (0.5–20 \(\mu\)M), and are performed as described for single-turnover conditions. The cleavage rates (\(v_t, \mu\)M min\(^{-1}\)) are determined at various substrate and inhibitor concentrations. Lineweaver-Burk, or reciprocal plots of 1/\(v_t\) and 1/[S] at all inhibitor (\(I\)) concentrations, are plotted, and the slopes and intercepts calculated by weighted linear regression analyses.

6.4 Three-dimensional Structural Information

6.4.1 Binding Shift Assay
Nondenaturing electrophoresis is commonly used in resolving the isomers that result from the folding of ribozymes. Moreover, kinetic parameters, such as equilibrium dissociation constant (\(K_d\)), the association and dissociation of substrate and product (Figure 5b), can be determined by this assay.\(^{19}\)

6.4.1.1 Materials and Methods The equilibrium dissociation constants can be determined as follows. Various ribozyme concentrations, ranging from 5 to 600 nM, are individually mixed with trace amounts of end-labeled substrate (<1 nM) in a 9-\(\mu\)L solution containing 50 mM Tris-HCl pH 7.5. This reaction is then heated at 95°C for 2 min and cooled to 37°C for 5 min prior to addition of MgCl\(_2\) to a final concentration of 10 mM in a manner similar to that of a regular cleavage reaction. The reactions are incubated at 37°C for 1.5 h, at which point 2 \(\mu\)L of sample loading solution (50% glycerol, 0.025% of each bromophenol blue and xylene cyanol) is added and the resulting mixture electrophoresed through a nondenaturing polyacrylamide gel (20% acrylamide with a 19:1 ratio of acrylamide to bisacrylamide, in 45 mM Tris-borate pH 7.5 and 10 mM MgCl\(_2\) buffer system). The gels are pre-run at 20 W for 1 h prior to sample loading, while the actual electrophoresis is carried out at 15 W for 4.5 h at room temperature. Quantification of bound and free substrate molecules is performed following exposure of the gels to a phosphorImaging\(^\text{TM}\) screen.

6.4.2 In Vitro Evolution
An in vitro selection procedure can be used for the identification of important residues in the structure of delta ribozymes.\(^{30}\) A pool of trans-acting ribozymes with sequences that have been randomized are produced from synthetic DNA templates using T7 RNA polymerase. In each selection cycle, the inactive ribozyme–substrate complexes can be separated from the active complexes using a biotinylated substrate against avidin. Using this procedure, the nucleotides essential for maintenance of the activity of trans-acting delta ribozymes were identified.\(^{30}\)

6.5 Data Analysis

\(\Delta\)Delta ribozyme is able to catalyze the cleavage of an 11-mer RNA substrate under both single- and multiple-turnover conditions.\(^{18-19,31}\) In both cases only small differences in the kinetic parameters are observed in the presence of either magnesium or calcium as cofactor. Under multiple-turnover conditions, the catalytic efficiency of the ribozyme (\(k_{\text{cat}}/K_M\)) is higher at 37°C than at 56°C.\(^{17}\) The cleavage reaction seems to be limited by the product release step at 37°C, and by the chemical cleavage step at 56°C. Substrate inhibition is detected at high concentrations of the 11-mer substrate. The 3′-hydroxyl group adjacent to the scissile phosphate is involved in binding with the ribozyme, while the essential cytosine residue of the J4/2 junction has been shown to contribute to substrate association. The kinetic pathway of delta ribozyme is believed to involve a conformational transition step that is essential for the formation of the active ribozyme–substrate complex (Figure 5b).

7 CONCLUSION
In addition to fundamental methods for the ribozyme structural analysis, several advanced protocols are being
developed for determination of the structure–function relationship of ribozymes. For example, X-ray crystallography, nuclear magnetic resonance and in vitro selection of RNA molecules have provided the scientific community with considerable information. We believe that these topics should be reviewed by experts in those particular domains.

1 INTRODUCTION AND BACKGROUND

The landmark structure of double-helical DNA was discovered using X-ray diffraction data obtained from natural fibers.\(^1\,^2\) In fibers, the helices are lined up in two-dimensional arrays. The third dimension is often indeterminate because the sample is heterogeneous in length, the helices do not line up in register if the length of every molecule is the same, or the helices have rotational disorder. Helices give characteristic X-ray diffraction patterns, such as the cross pattern of B-DNA, that make it possible to derive the pitch, rise, and number of residues per turn. The data to parameter ratio is low and therefore structures are determined by creating models and then calculating whether these models match the data. The inherent nature of the method is that one derives averaged structures. By using chemically synthesized samples with defined sequences, it has been possible to determine sequence–structure relationships for DNA and RNA. For example, it has been demonstrated that GC-rich sequences are in the A conformation whereas those that are AC-rich are more likely to assume the B conformation. It has also been possible to discover quaternary structures that have been validated using single-crystal methods. An excellent example is the quadruplex structure of poly G\(^3\) that was first discovered in fibers, and then seen in single-crystals. This unusual structure is thought to be a feature of chromosomal telomeres.\(^4\)

The first determinations of single-crystal structures of nucleic acids were published in the 1970s – significantly later than those of proteins. The main reason for this lag was the lack of pure material in sufficient quantity for crystallization. The crystal structure of tRNA was determined using X-ray methods in 1973\(^5\) and was the first, and for a long time the only, biological RNA whose structure was determined. The ability to synthesize and purify oligonucleotides made it possible to determine their structures. The very first dinucleoside phosphate crystal structures provided a great deal of information about the conformational flexibility of nucleic acids.\(^6\) Then in 1979, the first crystal structure determination of more than a full turn of DNA was published and gave rise to more than two decades of research on nucleic acid fine structure.\(^7\)

In this article we outline the steps involved in sample preparation and structure determination of nucleic acids. At the end we summarize some of the highlights of the more than 500 structures determined using single-crystal X-ray methods.

2 DESCRIPTION OF METHODS IN SINGLE-CRYSTAL WORK

2.1 Sample Preparation

DNA samples are most often chemically synthesized using automated methods. Purification steps usually include the use of reversed-phase high-performance liquid chromatography followed by ion-exchange chromatography. RNA samples with fewer than 20–25 nucleotides can be also synthesized chemically. However, longer sequences require the use of enzymatic methods that involve transcribing the RNA from a DNA template using T7 polymerase.\(^8\)–\(^10\) These methods, however, do not always produce homogeneous samples and further processing of the sample using ribozymes has been employed.\(^11\,^12\) Once the sample is made, it is
purified using both high-performance and fast protein liquid chromatographic methods. The preparation of RNA requires meticulous laboratory practices in order to ensure that the samples are not degraded by nucleases. This entails the use of autoclaved glassware and very high-quality chemicals. Thus, the preparation of RNA that is both pure and in large enough quantities for crystallization is significantly more difficult than for DNA.

2.2 Crystallization

The single-crystal method requires single, well-formed crystals that diffract well. The optimum size is about 0.2 mm on each side, although it is possible to use even smaller samples with the use of intense radiation sources. Oligonucleotide duplexes are sometimes difficult to crystallize in a form suitable for diffraction because the duplexes form quasi-infinite helices or even fibers. Sometimes an apparently beautiful crystal that looks well formed externally does not diffract at all, presumably because the molecules have not lined up in a lattice or have rotational disorder.

Generally, DNA crystals are grown using the vapor diffusion hanging drop method in which a drop of a solution of DNA is placed on a coverslip that is inverted over a reservoir containing the precipitating agent. The components of the drop usually include spermine, MgCl₂, sodium cacodylate, and a low percentage of methylpentanediol (MPD). The reservoir contains a higher percentage of MPD. Crystallization usually occurs within a few days. As shown in Figure 1(a) most DNA structures have been crystallized with MPD; attempts to use other agents have not been very successful.

Crystallization of oligonucleotides of RNA is done using procedures very similar to those used for DNA. Longer sequences of RNA including ribozymes and tRNA have been crystallized using a larger number of conditions than have been successful for DNA. Sparse matrix screens have been developed that allow the exploration of a broader range of conditions for RNA crystallization in a manner similar to that which has been employed for proteins. Figure 1(a) and (b) shows that whereas MPD is the universal precipitating agent for DNA, a larger number of precipitating agents have been used for RNA.

2.3 Data Collection

Once a crystal has been obtained, it must be mounted for data collection. For data collection at temperatures between room temperature and freezing, the crystal is put into a sealed capillary with a small amount of mother liquor. Increasingly, however, crystals are flash frozen. This makes it possible to collect an entire data set from a single-crystal since it will not decay in the X-ray beam.

Once the crystal has been mounted, data are collected. Over the years, the methods for data collection have changed considerably. Whereas in the past data were collected using a sealed tube and a diffractometer, nowadays almost all data are collected using a rotating anode which supplies a more intense source of X-rays and either an image plate or multiwire area detector (Figure 2a–d). Although most nucleic acid crystals do not usually require the use of synchrotron radiation, several structures have been determined using data from these sources. It is expected that as the demand for higher resolution information grows, the use of synchrotron data for these samples will increase. Data for protein–nucleic acid complexes are increasingly being obtained using synchrotron sources because of the improved resolution of the data and because of the possibility of using multiple anomalous dispersion (MAD) phasing for the structure determinations.

The resolution of the data determines how accurate the model of the structure will be. The resolution of DNA structures ranges from 0.9 to 3.25 Å with the average being around 2.2 Å (Figure 3a and b). Given the relatively small size of these molecules, these resolutions are relatively low. RNA structures tend to have even poorer resolutions, which may be because of the presence of many flexible loops.
2.4 Structure Determination

The challenge in X-ray crystallography is to obtain the phases of the reflections. Once the phases have been obtained, electron density maps can be calculated. From these maps one can trace the atomic structure of the model. Very small molecules can be phased using direct methods based on reflection statistics. Nucleic acids are in general too large and their resolution is too low for these methods to be used. The very first DNA and RNA structures were solved using isomorphous replacement methods in which heavy atoms are introduced into the lattice. A popular way to do this is to introduce brominated cytosines or uracils into the sequence. For larger and more globular molecules, heavy metals have been soaked into the crystal. Once these heavy atoms have been located, they are used to phase the reflections. This is the most unambiguous way of directly determining the positions of the atoms and is the least likely to lead to incorrect structures. Once a model has been determined for a particular DNA or RNA type, molecular replacement methods are often used for phase determination. In this method, a model of the structure is rotated and translated in the cell until
Figure 3 Distribution of resolution for oligonucleotides with length > 4. (a) RNA; (b) DNA. (Data and figures were generated from NDBQuery.\textsuperscript{(13)})

the model fits the data. If the model is very good, this method works well and gives reliable results. Although molecular replacement has been used with great success for helical DNA, it is possible to obtain incorrect results because of the hypersymmetry of the helix. Hence it is important to carefully evaluate the results of such determinations.

2.5 Refinement

Nucleic acid structures are refined using programs that fit the model to the experimental reflection data; to reduce the number of variable parameters, geometrical restraints are applied by restraining the bond distances and angles to chemically reasonable values. Careful fitting of the electron density maps is also done with electronic visualization programs such as FRODO\textsuperscript{(19)} or O\textsuperscript{(20)}. Central to the use of these programs is the availability of dictionaries containing standard values for the restraints and descriptions of the topologies of the molecules; the popularity of certain programs for nucleic acid refinement matched the availability of these dictionaries. CORELS\textsuperscript{(21)} which was developed for the refinement of tRNA, was superseded by NUCLSQ\textsuperscript{(22)} which was an adaptation of PROLSQ\textsuperscript{(23)} for nucleic acids. For a long time, this program was the one of choice. X-PLOR\textsuperscript{(24)} which was enormously popular for proteins, did not begin to be used extensively for nucleic acids until an appropriate parameter file for the nucleic acid force constants was developed\textsuperscript{(25)} (Figure 4a–c). The use of $R_{free}$ in which the $R$ factor for a subset of reflections is monitored as the model is changed has helped to improve the quality of nucleic acid structures. As the resolution of structures begins to improve to values below 0.8 Å, full matrix least-squares methods will begin to be used and the program SHELX\textsuperscript{(26)} is likely to gain in usage for macromolecules (Figure 5).

For all the nucleic acid structures in the Nucleic Acid Database (NDB),\textsuperscript{(28)} the measure of the fit of the model to data, known as the $R$-value, ranges from 0.07 to 0.25 and the mean value is about 0.18. Although it would be expected that there would be some correlation between resolution and $R$-value, there is not. By most criteria, the refinements of nucleic acid structures are very good with few anomalies present.

2.6 Analysis of the Results

Once the structure has been determined, there are a variety of analyses that are done to assess both the quality of the structure and the important structural features. In this section, we present a description of these analyses.

2.6.1 Structure Quality

Quality checks for nucleic acid crystal structures are done when the coordinates are deposited in the NDB, which is a searchable archive of nucleic acid structures. The average deviations of the valence geometry from standard values are calculated. In general, these values are $<0.02$ Å for the bond distances and $<1.5^\circ$ for the angles. These values are more of an indicator of the applicability of the dictionary that was used for refinement than of the actual quality of the structure. Individual values that deviate more than 4σ
from these averages are also calculated. Intermolecular contacts within the asymmetric unit and in the unit cell are determined. If there are crystal contacts that are smaller than 2.2 Å, and there are no errors in the cell dimensions, this is an indication that there is a problem in the structure; in general, there are very few instances of these sorts of errors in nucleic acid structures. The chiralities of the asymmetric carbons are also calculated. These types of chirality errors are rarely seen in nucleic acid crystal structures although they have been observed in nuclear magnetic resonance nucleic acid structures.\(^{(29)}\)

Finally checks are made of the match of the model against the experimental reflection data.\(^{(30)}\) The values of these \(R\) -factors are compared with those reported by the author and in most cases there is little difference between them.

2.6.2 Conformational Analysis

There are seven rotatable bonds in the backbone of nucleic acids (Figure 5) and five in the ribose sugar. The torsion angles for these bonds are different for the three classes of DNA double-helical duplexes: A, B, Z.
2.6.3 Base Morphology

The base pairs in duplex DNA and RNA are not planar (Figure 8). Indeed, it is common for some pairs to have a large propeller twist so that the base pair of one step can form hydrogen bonds with the base pair of the next step. In addition, there are parameters that describe the relationship of the base pairs in succeeding steps. The step parameters that are most useful in describing nucleic acid structure are roll, twist, and slide. For perfectly canonical B-DNA these values are approximately 0, 36, and 0°, respectively. The values for slide and twist are lower in A-DNA (Table 1). Individual structures can deviate widely from the ideal B- or A-DNA models. In the highly kinked DNA of CAP–DNA complexes, for example, the values of roll and twist deviate significantly. Several different algorithms have been developed to calculate these base morphology parameters. All of these programs yield similar results, although some subtle differences do exist. Attempts to develop a sequence-specific code for these parameters have been partially successful; it will not be possible to have a reliable set of values for the base morphology parameters for each of the 10 unique base steps in DNA until high-resolution data are obtained.

2.6.4 Hydration

The very first studies of DNA highlighted the importance of the humidity in determining the molecular conformation. B-DNA occurs in high humidity and A-DNA at lower humidity. The crystal structures of nucleic acids have demonstrated certain hydration patterns including other classes of DNA structures and for single stranded RNA molecules have not yet been established but it is likely that they will be significantly broader.

3 SURVEY OF KEY RESULTS

3.1 DNA

All the DNA structures determined thus far have been of synthetic oligonucleotides ranging in length from 2 to 16 nucleotides (Table 2). The largest set contains self-complementary dodecamers, which have been modeled after the first B-DNA structure whose sequence is CGCG-CAATTCGCG. Unlike the canonical structure derived from fiber work, this structure demonstrates unique characteristics for each step in the sequence. For example, the A–T base pairs have high propeller twist and the stretch of A sequence is very straight. The structure also shows an asymmetric bend. This template was used to explore the effects of modifications and mismatches and drugs on the structures of DNA; more than 50 structures of this type have been determined. Virtually all of the dodecamer structures fall into a single-crystal form. The advantage of this is that one can explore a variety of sequence–structure relationships while keeping the packing arrangement constant. A disadvantage is that one can
Figure 9 The hydration patterns observed in B-DNA. The hydrogen bonds are shown as dashed lines. (a) The spine of hydration in the minor groove of d(CGCGAATTCCGCG)_2 (BDL001). The first shell waters are hydrogen bonded to the purine N3 and pyrimidine O2 atoms and are shown as large spheres. The bases are color coded: green = guanine; yellow = cytosine; red = adenine; blue = thymine; other residues and drugs are black [except in (c), which is colored by strand].
The dodecamer and decamer structures are amenable to the binding of drugs in the minor groove, making it possible to gain insight into molecular recognition. More than 40 structures have been determined in which the drug nestles into the minor groove. In some cases, the drugs bind in pairs. There are also several examples of intercalating drugs such as daunomycin and actinomycin whose planar groups fit between two base pairs and cause the DNA to unwind. Both of these drugs also have prosthetic groups that further interact with the DNA.

A-DNA structures have also been extensively studied and reviewed\(^{(47)}\). In general there are greater variations in the helices, probably because of packing effects. The packing of these molecules is very characteristic with the minor groove of one duplex butting up against the phosphate backbone of another.

One of the most surprising results of the explorations of DNA structure was the discovery of the left-handed Z-DNA [for a review, see Ho and Mooers\(^{(48)}\)], which exists in solutions containing very high salt or alcohol.

Figure 12 Some examples of RNA structures. levels. The correlates of this conformation in crystal form are the presence of alternating pyrimidine and purine sequences and a strand length of six. Almost all the Z-DNA structures pack with the helices lined up one atop the other.

DNA can also form quadruplexes (Figure 11a–d). Two different types have been observed. In one type the guanines form quartets \([e.g. \text{UDF036}^{53}]\). In the other cytosines from two strands intercalate between cytosines of the other two strands \([e.g. \text{UDD023}^{54}]\).

Within these major classes of DNA structures, many special features have been observed. These include bulges caused by extra bases in one strand, frayed ends or single base overhangs. These latter features enable the ends of the DNA molecules to associate in novel ways forming for example triplets. Interestingly, the one major structural type that has never been observed in crystals is the DNA triple helix.

### 3.2 RNA

The very first oligonucleotide structures to be determined were RNA dinucleoside phosphates and for a long time these were the only oligomers studied using X-ray methods. With the availability of methods to prepare, purify, and crystallize RNA, increasing numbers of RNA structures are appearing.

Duplexes of RNA with Watson–Crick base pairing have been crystallized; these have the expected A conformation (Figure 12a–d). In some of these cases, sequences were crystallized in order to model RNA hairpin stem-loops; instead, A-type helices were seen in the crystal.\(^{55}\) To accomplish this, these helices have stretches of mismatches that form internal loops. Furthermore, the mismatches seen are not simply ones involving the bases themselves but also utilize water molecules. A summary of the types of mismatches and internal loops is given elsewhere.\(^{60}\)

Two classes of biological RNA molecules have been crystallized: tRNAs\(^{61}\) and ribozymes.\(^{57}\) The tRNA molecules are single stranded molecules in which a cloverleaf type secondary structure folds into an L-shaped molecule with extensive base stacking and tertiary hydrogen bonds. These hydrogen bonds form between conserved bases and thus are key structural elements in all tRNA molecules. The structures of hammerhead ribozymes, like the structures of tRNA, have extensive base stacking and exhibit some of the same unusual conformation and hydrogen bonding features. The structures of both tRNA and the hammerhead ribozyme have provided testable models for understanding their biological functions. Base stacking, tertiary hydrogen bonding interactions, and more conformational motifs also dominate the spectacular structure of the P4–P6 domain of the group I intron ribozyme.\(^{59}\) Although it is certain that there will be more RNA structural elements forthcoming, it should now be possible to classify systematically those that have been seen thus far in order to facilitate modeling of larger RNA structures.

### 4 CHALLENGES FOR THE FUTURE

Although many structures have been determined, there are still many unanswered questions. In the field of DNA crystallography, the issue of how much the sequence determines the structure is as yet unknown. To be able to understand this, it will be necessary to determine the structures of the same sequences in different crystalline environments. The effects of complexation to proteins and drugs can only be answered by studying sequences alone and in complexes. Further, of course, in dealing with the level of fine structure inherent in defining base morphology, there is a clear need for very high-resolution structures. RNA crystallography is still in its infant stage, and when fully developed it will allow us to understand more fully the complex rules that govern the folding of single strands into compact structures.

X-RAY STRUCTURES OF NUCLEIC ACIDS

1 INTRODUCTION

Surveys have shown that in the 1980s the production of powdered materials had an annual value in excess of US$10 billion,\(^{(1)}\) while more recent surveys showed that an estimated 25–30% of the total output value from the chemical industries was in the physical form of either powdered or agglomerated material.\(^{(2–4)}\) There is now an awareness, within many sections of the chemical industry, to the increasing amount of bulk powdered materials – in the form of crystalline solids, agglomerated or granulated powders, and processed or comminuted powdered materials – that are being produced year by year. The characterization of the particulate material produced – together with the handling and behavior of powdered material in bulk quantities – is therefore of paramount importance in the optimization of many multiphasic and multiparticulate processes. The variations in the behavior and dynamics of various types of processing, due to the presence of particulate material and the formation and generation of intermediate or final product particles within manufacturing can, in turn, produce particles with many different chemical and physical characteristics. This can be illustrated using lactose as an example. Lactose can be crystallized at different temperatures to produce particles of either \(\alpha\)-lactose (below a crystallization temperature of 93°C) or \(\beta\)-lactose (above a crystallization temperature of 93°C). These powders, although similar in their chemical make-up, have different physical properties, which show different compactability behavior due to the differences in surface forms.\(^{(5,6)}\) In some circumstances slight changes in operational temperature or rate of mixing, or changes in concentrations of ingredients within the process, can produce particles which are better suited to one end effect than to others. Characterization of powder surfaces by inverse gas chromatography (GC), coupled with the use of computer models of single-crystal slip planes, has resulted in the thermodynamic discrimination of various powdered surfaces and their modification to improve efficacious drug release. With advances in processing and the measurement of a variety of particle characteristics, this should ultimately lead to a situation in which a chemical process could be manipulated to “tailor-make” and design particles for a range of desired functions (M. Ticehurst and I. Grimsey, private communication, 1998).

Throughout this section emphasis is placed on the various and diverse methods and techniques for measuring the sizes of irregularly shaped particles. In general, measurement of irregularly shaped particles can be classified into one of three groups (see points 1–3 in the list that follows). An additional group, although...
not size-related, but still essential in the characterization of powdered materials and in the metrology of particle characterization, and which may be of more relevance when solid–liquid particle interfaces are considered is the parameter of surface area and porosity (see point 4).

1. Direct dimensional measurements, as seen with sieving and microscopy. These techniques are explained in more detail in Sieving in Particle Size Analysis.

2. Transport measurements. These techniques are explained in more detail in Sedimentation in Particle Size Analysis, and Centrifugation in Particle Size Analysis.

3. Rapid physical response measurements. These techniques are explained in more detail in

   - Electrozone Sensing in Particle Size Analysis
   - Light Scattering, Classical: Size and Size Distribution Characterization

   - Photon Correlation Spectroscopy in Particle Sizing
   - Field-flow Fractionation in Particle Size Analysis
   - Ultrasonic Measurements in Particle Size Analysis
   - Diffraction in Particle Size Analysis
   - Optical Particle Counting

4. Surface area and porosity measurements. These techniques are explained in more detail in Surface Area and Pore Size Distributions.

   The surface area and porosity characteristics of powders may both be calculated from low-temperature adsorption isotherms obtained by gaseous adsorption. The amount of available surface area is generally measured from the lower relative pressure range of the isotherm, while the degree and magnitude of the porosity within powdered or agglomerated material, in terms of macro- and mesopores, is usually derived from the section of the isotherm that has a relative pressure greater than 0.4. For micropores the whole of the isotherm is commonly used for analysis.

   In addition to those articles listed above, there are two other articles within this section; one illustrates the use of Filtration in Particle Size Analysis and the other addresses the characterization of Velocimetry in Particle Size Analysis.

1.1 Historical Background

The emergence of the modern-day discipline of powder technology and thus the measurement of irregularly shaped particles occurred at approximately the same time in North America, continental Europe and the UK during the late 1940s and early 1950s. However, it was believed by Heywood that powder handling and classification of naturally occurring sands and mineral ores can be traced to Egyptian times. The art of sieving in Elizabethan times, together with the settling of mined ores and the technical development of mineral dressings, has been vividly illustrated by Donald. This book traces the formation of one of the first English companies to manufacture an article (in this case copper) as opposed to solely trading abroad. German scientists were brought over to England to extract and smelt the copper ore extracted from mines located in Cumberland and Cornwall. The techniques of metal dressing used to separate, grade and purify the Elizabethan copper had initially been laid down, a few years earlier, by Agricola. A later publication by Ercker showed how ore could be taken from a furnace, stamped (crushed by water-powered mills) into hazelnut- or acorn-sized pieces (2 cm), separated, returnfaced for further purification, stamped again and then graded into a powder which had particles “ likeness to the size of meal” (150–250 µm).

The separation or mineral dressing of ores probably involved the same method of three dry sieving stages followed by three wet sieving stages as given by Agricola and Ercker. The description of the smaller sieves used was “a wooden tray with a wire bottom never occupied”. To place into perspective the amount of effort needed to get mined ores into a suitable state for chemical processing, it was found that the cost of mining, stamping and grading the copper was similar to the furnacing, melting and carriage costs of the final product.

One of the first publications dedicated solely to outlining the various mechanico-physical techniques for particle measurement was written by DallaValle. This was closely followed by a book by Herdan, which concentrated on the conceptualization of the statistics of particles by the combination of both number statistics and physical statistics, as seen in colloidal systems, to give rise to a new discipline called small-particle statistics. Rumpf was concerned with process technology in terms of the transformation of matter by different mechanisms. In chemical process engineering transformation of matter is deemed to occur by chemical reactions, while in thermal process engineering it is regarded as the transformation of thermodynamically defined phases. In both cases the system parameters of pressure, temperature, and composition follow the laws of thermodynamics. Rumpf, however, suggested that there was a third engineering technology that could characterize changes in the state of disperse systems and of mixtures consisting of particulate matter and continuous fluid phases. Rumpf created an area of academic and industrial interest termed mechanical process technology which was a forerunner.

do the discipline now known as powder technology. In reality, although a mechanico-physical unit-processing operation may precede and at times terminate a chemical and thermodynamic unit-processing operation, all three technologies are inter-related and essential to the transformation of matter into a desirable end product. Table 1 highlights some of the publications that have advanced the knowledge and technology of particle size analysis and powder characterization.

One of the first symposia on particle size measurements, which was to supply an intellectual interest and stimulus to the subject of powders and solid particles, was held in London in 1947 under the auspices of the Society of Chemical Industries and the Institution of Chemical Engineers. At the opening of this symposium it was stated that, as far as the President of the Institution was aware, no previous attempts had been made to survey or appraise the difficult subject of particle size analysis.

From that symposium, and with the efforts of a few internationally active powder technologists, an expansion in the field of particle size measurement occurred. This was coupled with a greater understanding and comprehension of particle size distributions, particle shape, particle shape distributions and the surface area of powders.

The disciplines of powder characterization and powder technology, which initially emanated from the UK and continental Europe (Table 1), have now become global in their ramifications and acceptability. The forms of particulate matter generated, fabricated, produced and processed have increased enormously, along with the technologies of measurement, since that 1947 symposium. One of the reasons for the dramatic changes in the types of instruments now available, and the use of a wide range of different physical, optical, electromagnetic, and at times electrochemical measurement systems, is due to the advances in computer technology. The amount of data that can be measured, and the speed at which they can be collected, by new and novel measurement systems connected to plant items, has in recent years opened up new frontiers to the powder technologist. Computer-assisted particle measurement instrumentation not only aids the collection of data but also gives the powder technologist the ability to carry out advanced statistical analysis of data gained from real-time measurement systems. The integration of computers to control and automate processing plants, be they chemical, mechanical or powder bulk handling, is extending the original role of off-line laboratory particle measurements to one in which measurements of particle sizes are made on-line and in-line in real time within a chemical processing plant. The ultimate measurement system, which may not be dependent solely on the measurement of particle
size, would be an in situ array of sensors, within a reactor or processing unit. Such a system could detect and characterize one or more particle parameters to control a dynamic particulate process and produce a specifically desired end product. Current research, which is now multidisciplinary as well as multi-authored, is adopting a wider selection of physical criteria than that initially used for off-line laboratory analysis. Through the use of ultrasounds and optical and tomographic sensing techniques, advances have been made to implement in-line particle characterization in the armory of the particle/powder engineer. Microelectrical resistance tomography has recently been used to find a solution to two problems that were affecting the advancement of particle characterization and the control of particulate processes. A novel in situ method, using resistance tomography, has enabled the measurement of both the size and the shape of a flowing particulate suspension to achieve what is termed an “electrical texture fingerprint” of the flowing particles. Use of similar tomographic sensors has also facilitated the access of multivariate data to enable the control and optimization of multiphase particulate and chemical processes.

It should, however, be noted that particle size measurement by itself has little or no meaning, unless the reason for the measurement is also specified.

### 1.2 Selection of an Instrument for Particle Characterization

One of the most important factors that must be borne in mind when approaching any particle size analysis is that, although there are many ingenious, sensitive, reliable and repeatable techniques, no one method can be regarded as perfect. Tabular procedures and flow diagrams have been published that help with the process of choosing an appropriate particle size measurement technique, but a compromise usually has to be made, in terms of cost and time available, to achieve the best particle characteristic or measurement of particle size.

To these ends several techniques are discussed in this encyclopaedia, to illustrate the diversity that exists and which can now be used by the powder technologist.

The choice of a particle size measurement technique is dependent upon the accuracy of the measurement required and the circumstances to which the measurements are to be applied. This rationale was introduced and emphasized by Heywood, who is regarded as a founding father of powder technology in the UK, with the words:

However, it must be realised that particle size analysis is not an objective in itself but is a means to an end, the end being the correlation of powder properties with some process of manufacture, usage or preparation.

This point was also made by Herdan, who stated about fifty years ago that:

Knowledge of the size characteristics of particulate matter is generally of little value in itself; but particle size measurements are often made to control the quality of the final product, because certain sizes may be correlated with certain desirable properties of the product.

This statement was made at a time when Herdan was interested in the statistics of small particles (particles that were generally classified as being either in the sieve or subsieve range). In terms of physical dimensions, the lower size limit for a woven wire sieve was then customarily recognized as being 75 µm, while subsieve-sized particles had dimensions below this value.

A particle primarily refers to a object that has a physical boundary regardless of its finite size. Because a particle is a discrete portion of matter that is usually regarded as being small in relation to the space in which it is encompassed, the upper size limit of an individual particle is therefore arbitrary. With this definition, planets, rocks, boulders, aggregates, powdered particles, colloids, molecules, and submolecular and atomic entities may all be regarded as being technologically important to a powder technologist.

For practical purposes, however, an arbitrary definition of the size of powder particles has been chosen so that “a powder shall consist of discrete particles of any material with a maximum dimension of less than 1000 µm (=1 mm)”.

The lower limit these days, because of the introduction of ultracentrifugation, field flow fractionation, ultrasounds, light scattering and X-ray scattering, is commonly taken to be in the submicrometer to colloidal dimensional range (1 nm) (Table 2). With the advent of “nanotechnology” this lower limit is being superseded, and instrumentation is being developed to measure particles of this size.

Because a particle can be defined and described as a discrete entity of matter it is possible to obtain size distributions of populations of solid, liquid or gaseous particles in solid, liquid and gaseous phases by using an appropriate measurement technique.

Although particle size is an important factor in the determination of how a particle will behave, the measurement of that irregularly shaped particle characteristic may be achieved by several different physical techniques, depending on the final objective of the measurement. It is unusual to measure only one particle, thus particle sizing and powder characterization are generally described in terms of a particle size distribution. According to one glossary of powder technological terms, a particle size distribution may be described in terms of the size and frequency of particles in a population, or alternatively as the functional relationship between a quantity of particles...
and a dimensional measurement of the irregularly shaped particles.

2 SAMPLING OF A REPRESENTATIVE ALIQUOT OF POWDER

Since off-line quality control of a particulate system is retrospective, there is always the possibility of inaccuracies in solid sampling and nonrepresentation of the bulk material.

The purpose of sampling is to obtain a sample (or samples) from a bulk material that is representative of the bulk material in some desired property, which can be particle size, surface area or chemical composition. A perfect sample from a bulk powder is one which contains all the constituents of the bulk powder in exactly the same proportions as the bulk powder. In other words the bulk powder is perfectly mixed and can be regarded as a homogeneously mixed powder.

If a material is believed to be homogeneously distributed in the bulk, then simple random sampling, using a thief sampler or a spoon to obtain samples from anywhere in the powder, is acceptable. Most materials, however, will not be homogeneous, and methods must be devised to achieve a sampling efficiency akin to that theoretically possible from the random variation to be expected under ideal conditions.

There is, however, always a problem with sampling and the taking of an aliquot from a powder, because any attack on a homogeneously mixed powder will cause particle segregation if the powder is free-flowing and noncohesive. There is also the possibility that even if the powder has a degree of cohesiveness there will be particle movement within the powder mass and segregation will again ensue.

Sampling is therefore an error-generating procedure and no sample provides more than an estimate of the truth or reality of a situation.

In the literature on solids mixing, the word “sample” has been given a different meaning from that usually intended in textbooks on classical statistics. In the literature on powder technology there is an established practice of using the term “sample” to refer to a number of contiguous particles removed from some position in a bulk powder, rather than to an integral unit as presupposed in classical statistics. A representative sample size must thus contain a certain number of particles. This ensures statistically that the sample taken is representative of the whole powder. For example, if 1 g of powder is taken from an industrial powder which has a particle density of 2 g cm$^{-3}$ (2.0 $\times$ 10$^{-3}$ kg m$^{-3}$) and the mean particle size in the powder is assumed to be 100$\mu$m, then the number of particles present in each 1 g aliquot would be in excess of 10$^6$ particles.

2.1 The Classical Statistical Concept of Sampling

Because there are always many particles in a sample mass taken from a powder, a common approach is to regard powder sampling as being based on number statistics, as seen in many textbooks on classical number statistics. From the viewpoint of classical statistics the sample taken is visualized as an entire single entity and not as a collection of variously sized particles in that powder sample. In classical statistics, however, it is normal to obtain an estimate of some parameter of the single sample, and therefore obtain an interpretation of the deviation of that individual “sample” from a series of “samples” that all have a simple distribution of values. In addition an arithmetic average or mean, from all the samples, can be evaluated and deviation from that mean observed.

The range of deviation, degree of dispersion or spread of values around a mean can readily be obtained from number statistics, assuming the initial values are normally distributed about a mean value.

In the case of the probability of a number occurring on the throw of a die or dice the variation and distribution of the numbers could be expressed as a binary or Bernoulli distribution. As the number of events increases, for example when considering a million events or the thousands of particles in a gram of powder, a normal (Gaussian or bell shaped) distribution can be assumed. The representation of such Gaussian distributions can then be expressed in terms of

1. standard deviation, or a measure of the extent of a set of numbers dispersed about a mean;
2. variance, or the square of the standard deviation (regarded as a more common alternative measure of dispersion);
3. coefficient of variation, which is the ratio of the standard deviation to the mean;
4. correlation coefficient, which is the ratio of the standard deviations of two variables.

An additional useful estimator that provides an indication of the accuracy of the average estimate is the standard error, which is defined as the standard deviation of the population divided by the square root of the number of items in the sampled unit.

When these classical statistics are applied to sampling it is assumed that all units of the population have an equal chance of being in the sampled unit.

There are several factors that should be considered prior to subdivision or sampling of a powder.

1. Flowability: An assessment of whether the material is free-flowing or cohesive should be made visually or by pouring it through a funnel with an orifice about 1 cm in diameter. This may be affected by other properties listed here.
2. Maximum particle size: The maximum particle size should be assessed. This will not usually exceed 1000 µm, but sample examination and subdivision procedures can be applied for larger particles.
3. Uniformity: The material should be examined to determine whether it contains particles of widely differing chemical nature, density or size, and an assessment made of its likely behavior during sample division.
4. Friability: The tendency of particles to break or erode during handling or under pressure should be assessed.
5. Moisture: The presence of high levels of moisture should be determined. This might be detected by a tendency to coalesce under pressure. A moisture determination may be of value where hydroscopic or efflorescent materials are concerned.
6. Aggregation: The material may show signs of inherent aggregation either on standing or on handling. The presence of aggregates may be detected by a simple microscopic examination. This will also reveal the presence of very small particles which could affect the behavior of the sample.
7. Chemical nature: A knowledge of the chemical nature of the material is necessary to assess its possible reaction with the atmosphere and the working surfaces. The hazards associated with handling the material should be known.

### 2.2 Sampling Reliability

In the real world, the particle size distribution in a powder does not always show, or even approximate to, a normal or Gaussian model, so conclusions based on classical statistics with a simple mathematical model may not be valid. The objective of sampling is therefore to obtain one or more samples of the bulk material that are representative of that material in some chosen particular. To ensure accuracy, which can be regarded as a measure of the degree to which a value or estimate approaches a “true” value and which denotes an absence of bias, the sampling operation must be free of systematic errors.

To obtain precision, which is the measure of the ability of a procedure to yield the same or near identical results from successive treatments of the same sample material, the random errors should be narrowly dispersed about the mean. A well-designed sampling procedure is therefore one in which errors arising from (1) theoretical differences between the operation and the model, and (2) differences between the actual operation and the model, have been minimized.

These errors, which occur in every sampling procedure, can be separated into those that cannot be altered and those that can be minimized. An error that cannot be altered and is inherent in every sampling technique is a fundamental error (FE). This type of error results from the natural variance or inherent random nature of a powder because of the heterogeneity of the particle population. It possesses two important features:

1. it is the only sampling error that cannot be suppressed, as it occurs in ideal sampling;
2. it can be estimated beforehand.

FE can be mathematically expressed as shown in Equation (1).

\[
s^2(\text{FE}) = \frac{C_d b^3}{m}
\]  

where \(s^2(\text{FE})\) is the variance of \((a_r - a_b)/a_b\) if \(a_r\) and \(a_b\) are content values of sample and bulk batch respectively; \(C\) is the sampling constant, a function of the material’s properties, which can be determined from knowledge of the physical characteristics of the particle assembly – particle shape factor, size distribution and mass fraction of the size class under investigation – as well as the statistical variance of the sampling error desirable in the sampling procedure – \(m\) is the sample weight; and \(d\) is the size of the square mesh sieve required to retain 5% of the particles or a specified percentage of a specified size range of particles.

FE and its variance can be reduced by increasing the sample weight and reducing the value of \(d\). The total model sampling error can be reduced to FE by taking individual particles at random or from part of a homogeneously distributed bulk.
The segregation error (SE) is the expression of the distribution heterogeneity of the bulk to be sampled. It depends on:

1. constitution heterogeneity (as for FE), because the larger the variation in particle size/mass, the greater the segregation;
2. segregation, or the demixing of differently sized particles into zones that then cause the powder to be nonhomogeneous or demixed;
3. weight of the increments (the greater the increment, the larger the group of particles taken each time).

Gy[29] found that the variance of the SE, $s^2(\text{SE})$, can be expressed as equivalent to a segregation factor times a group factor, where the segregation factor is zero for a homogeneous distribution and the group factor is zero for a single particle. To minimize SE, sampling should be made on a bulk material that is as homogeneously distributed as possible, with increments that are as small as possible (although a certain minimum weight is required to limit operational errors).

Another error that can significantly affect the representation of the bulk material by the sample material is the integration error (IE). IE is caused by the type of sampling strategy used to obtain a mass of sample. This error is introduced by the variability in the bulk and the spacing (in distance or in time) between the increments. Thus to reduce IE one should (1) reduce variability by homogenization of the bulk, and (2) sample in the whole space occupied by the batch (or during the whole time), taking increments as close together as possible.

Because IE is related to the type of sampling undertaken, IE can be minimized by using systematic sampling if the error does not vary periodically, or stratified random sampling if some periodicity is present, and by taking the greatest possible number of increments.

Analysis has shown that all theoretical errors, except one, can be reduced to small values by using homogeneous bulk material, by maintaining a constant rate of flow, and by taking a large number of small increments to form the sample. The exception is due to the heterogeneity of the particle population. This error exists even in ideal sampling, and although it cannot be removed, it can be estimated.

The three types of sample strategy in use are

1. random sampling
2. systematic sampling
3. random stratified sampling.

When the bulk material is not homogeneously distributed, random stratified sampling has been recommended to guard against the possibility of cyclic variations in bulk quality. In a continuous delivery operation, sample increments are taken at random times during successive standard time intervals (strata) spanning the whole process. For static bulks the strata could consist of wagon-loads, or bags, or a number of bags.

2.3 Selection of Sampling Methods

The objective in the selection of a specific sampling technique prior to particle characterization is to obtain from the laboratory sample a test sample or test portion that represents the laboratory sample as closely as possible. The practice of sampling is based on the premise that there is a theoretical possibility of dividing a sample into smaller samples or portions without the introduction of biased errors. The collection of data from every sample or position in a sample is expected to embrace the mean value of a characteristic of the sample. It must also permit an estimation to be made of any variation of the measured characteristic throughout the sample.

In any homogeneous sample any aliquot or subdivision of the sample will precisely represent the sample as long as the sampling technique does not impart any systematic bias to the subdivision procedure.

When a laboratory sample is known to be a true homogenized bulk, conceptually, any volume selected, without demixing or the separation of particle sizes, will constitute a perfect sample. However, since any particle has a finite volume and real powders have a distribution of sizes, there has to be a minimum volume withdrawn from a homogeneous mixture to obtain both a representative and measurable sample. With such a homogeneously mixed material the technique of scoop sampling could be used to obtain a test sample or a test portion. To ascertain if the laboratory sample is homogeneously mixed with respect to a given characteristic it has to be established that the mean values of all subdivisions are identical in that characteristic.

To verify this homogeneity, several samples or portions must be chosen at random and tested, which in itself is a sampling technique. In reality no material can be deemed to be homogeneously mixed unless sampled.

To assume a homogeneous mix prior to sampling and then to use the method of scoop sampling as a sampling technique can only be justified if, from past experience, the assumption of a homogeneous material is correct and scoop sampling or coning and quartering gives results that are comparable to more sophisticated sampling methods.

When a heterogeneous mix occurs on subdivision, because particles are impeded in their movement throughout the particle assembly, a concentration of certain sizes or characteristics can occur in local positions. The sampling technique must therefore prevent or overcome segregation of these characteristics into local concentrations.
Heterogeneous material is material in which a spot sample, taken from the laboratory sample, will have a significantly different value of the characteristic under investigation from the mean value of the laboratory sample. Unless it is known otherwise, it is advisable to assume that all laboratory samples are heterogeneous and to use a sampling technique that subdivides the laboratory sample into subdivisions that are all representative of the laboratory sample.

Very rarely will the bulk material be homogeneous with regard to the characteristics to be tested. It is a frequent requirement in specifications that a measurement of this inhomogeneity be made. It is then necessary to take several different definitions and masses of samples; the number and size of which will depend on the quantity and particle characteristics of the material.

British Standard (BS) 3406 defines the following powder samples:

1. Gross sample: the final sample obtained or prepared from bulk material.
2. Laboratory sample: sample delivered to a laboratory. May be a gross sample.
3. Spot sample: a sample taken from a specified place in the bulk material. May be a gross or laboratory sample.
4. Test sample: a sample prepared from the laboratory sample and from which the test portions are withdrawn.
5. Test portion: that portion withdrawn from the test sample and entirely used in the test or observation.

The minimum size of sample to be taken to represent the bulk material can be derived by assuming that all errors are zero except that due to the spatial distribution of the differently sized particles themselves.

### 2.4 Attainment of a Test Sample

In general it is not possible to calculate the sample mass required for a given precision because, of all the sampling errors, only the FE can be determined. Assuming that an ideal sampling situation exists and Gaussian distributions predominate, a relation between the variance, sample size, and component proportions will, however, enable the minimum sample size to be determined (Table 3).[30–34]

The homogeneity definition requires specification of the size of the test sample or test portion because homogeneity implies that the variability between samples or portions is either negligible or too small to be measured. This should not be taken to imply that homogeneity persists as material is further subdivided. An optimum sample or portion volume must therefore be used which is capable of giving the necessary information about the material it represents.

#### 2.4.1 Free-flowing Powders

With a free-flowing powder there is a greater tendency for segregation to occur than with non-free-flowing, cohesive powders. It is therefore advantageous to sample from a moving stream. This can be accomplished by using a rotary sampler. Various designs exist in this category of sample dividers, but most consist of one or more receivers placed on a turntable that rotates at a specific speed. This type of equipment is thus ideal for free-flowing nonfragile material, but at times can be used for non-free-flowing materials. The abrasion caused by the passage of particles through the sample divider may have an adverse effect on fragile material. A chute riffler can also be used for free-flowing powders.

#### 2.4.2 Non-free-flowing Powders

Although in some cases it may be possible to sample non-free-flowing material with a rotary sample divider or a riffler, in most cases it will be necessary with non-homogeneous and non-free-flowing powders to premix the powder. With such powders it may be advantageous to use a wet sampling technique. The coning process of the coning and quartering technique[28] is to ensure an adequately mixed sample prior to subdivision. The degree of mixing obtained by this technique can in some cases (depending on the chemical and physical nature of the powder), be enhanced by the presence of a small amount of liquid. Continuous handling of the solid is not recommended for fragile particles.

The actual operation of sampling a material stream requires care in design, to ensure that the full cross-section of the stream is sampled on every occasion, that no mechanism is in operation that preferentially accepts or rejects pieces of certain sizes, and that no loss of sample or gain of adventitious material occurs (Figure 1 and Table 4).

3 CHARACTERIZATION OF IRREGULARLY SHAPED PARTICLES

In many powder handling, powder production and powder related industries the sizing of particles is traditionally achieved by retrospective physical measurements of the sampled powdered material – off-line laboratory analysis. Off-line sizing of irregularly shaped particles and intermediate primary particles, from either batch or automated production, can only be confidently achieved when a representative sample has been taken from the process. The range of sizes measured off-line by modern instrumentation covers the majority of sizes encountered, from high-throughput, low-value products to low-throughput, high-value “high tech” products.

There is no single definition of particle size, as different methods of particle size analysis are based on a wide variety of different physical criteria.

In many textbooks (see Table 1) the particle size of an irregular solid is described in terms of the physical...
criterion used to measure the particle’s dimensions. Thus, in the past, if the method used to size particles was a mechanical sieving technique, the particle dimension was called the sieve size and had the symbol $d_t$, while if a sedimentation technique was used, the particle dimension obtained could be calculated and described in several ways, including as a free fall diameter, $d_f$, a drag diameter, $d_d$, or a Stokes diameter, $d_St$. ISO (International Standardization Organization) Standard 9276-1 \(^{35}\) now recommends that the symbol $x$ be used for particle size and that a subscript denote the equivalent diameter measured by one of the physical measurement techniques. For example, theelectrosensing zone method measures the volume of a particle and this can be identified by the symbol $x_v$, which is an equivalent volume diameter. Likewise $x_s$ is equivalent surface diameter, $x_w$ is equivalent settling diameter at either high or low Reynolds numbers, and $x_n$ is equivalent mesh diameter.

This, as can be imagined when only the term “particle size” was used, has relived some of the ambiguities that could and did lead to confusion when any attempt was made to compare the particle size obtained by one technique with a size obtained by a different physical technique. There is no physical or theoretical justification why any two irregular particle sizes measured by two different techniques should be comparable. A sieve size is not equivalent to a drag or Stokes diameter. This nonequivalence can be advantageous when used to describe the shape of particles, but not when trying to achieve a consensus on the dimensions of an irregularly shaped particle.

Table 5 shows seven arbitrary physical classifications of particle sizing techniques that have been used to measure particle size. Also shown is the descriptive diameter ascribed to the particles measured by that technique. The symbols and nomenclature for particle size and the methods used to obtain a measurement of irregularly shaped particles have recently been re-symbolized. Table 6 shows the new ISO-approved nomenclature. To overcome the confusion that can occur when “particle size” is not fully notated, an Expert Group under the auspices of the Bureau Communautaire de Référence (BCR) \(^{36}\) undertook a certification campaign to measure five powdered reference materials in the size range 0.1–1000 $\mu$m and to present the measured particle sizes graphically. It was consensually agreed that the classical treatment of size would be based not solely on physical criteria but on the concept of an equivalent sphere diameter and that the traceable fundamental units of length, mass and time would be used.

For the purpose of these BCR materials the size of the irregular particles was defined as the diameter of a sphere which is equivalent to the particle with respect to either its volume (volume diameter) or to its settling rate in a viscous fluid (Stokes diameter).

A sphere can be measured and defined by one single diameter, a cube by one length dimension and an oblongated body measured by in terms of length, breadth, and thickness. Since an irregularly shaped particle can have various lengths, breadths and thicknesses dependent upon the position of the measurement, it cannot therefore

be described or defined by a single or unique dimension and its size may be expressed in terms of the diameter of a circle or a sphere which is equivalent to the particle in some stated particle property (Figure 2). The particle size of an irregularly shaped particle has now been consensually denoted and defined globally\(^{35}\) as “the diameter of a sphere having the same physical properties: this is known as the equivalent spherical diameter”.

There are other definitions for particle size, such as those based on the openings of a sieve or on a statistical diameter such as a Feret’s diameter which is measured by image analysis (Figure 3). It should, however, be mandatory that whenever the size of a particle is stated an indication is given of how that particle size was defined and measured. The symbol designated to represent the size of the particle diameter or equivalent spherical diameter in the past has always been “\( d \)”. In many technological publications this is being superseded by the symbol “\( x \)” because ISO 9276-1\(^{35}\) has recommended that “\( d \)” now be replaced by “\( x \)” to denote an equivalent spherical diameter or a diameter of a sphere. Thus \( x_s = (d_v) = \) equivalent surface area diameter and

![Figure 2](image2.png)

3.1 Graphical Representation

Most modern instruments present the measurement results in graphical form, but at times it is necessary to express these results quantitatively so that only a single representative measurement is used and introduced into some particle system correlations and particulate models. Some of the simplest correlations reduce a particle size distribution to a single parameter. The statistical parameter calculated can be a mean size, a median size, or a modal size. These single averaged parameters can thus convey, by a single number, the order of the particle size involved within a distribution, but such a single parameter gives no indication of the spread of the distribution. The mean size is the average of the distribution. The median size, where half of the particles

\[ x_v = (d_v) = \text{equivalent volume area diameter}, \text{although this change in nomenclature is not mandatory.} \]
are smaller and half are larger than the median size, is the midpoint of the distribution and is often denoted by the symbol \( x_{50} \). Finally, the modal size is the size that occurs most frequently within the distribution and is thus the location of the maximum quantity within the distribution. Powders can, however, have more than one modal value and particle size distributions can be mono-, bi-, tri- or even multi-modal.

As powders are assemblies of particles, a powder can be characterized in terms of its distribution of particle sizes by a statistical parameter that is chosen to typify both the type of distribution and the average particle size within that distribution.

The distribution is usually determined either as a number distribution or as a distribution by weight, and the information may be displayed graphically either as a histogram or as a continuous distribution curve. ISO 9276-1 recommends that measurement of a distribution be graphically displayed as either a discrete density distribution, \( q_r \), or a cumulative distribution, \( Q_r \) (Figure 4). A cumulative distribution curve is used most often because the curves can be more easily interpolated and normalized. The word “density” denotes a statistical parameter akin to the frequency of an event in number statistics and should not be confused with the physical property of mass per unit volume.

Since a powder consists of many particles which have a range of sizes it is possible to mathematically describe that range of sizes using Equation (2)

\[
Q_r(x) = \int_{x_{\text{min}}}^{x} q_r(x) \, dx \tag{2}
\]

where \( x \) represents a particle size, \( Q_r(x) \) is the cumulative distribution, and \( q_r(x) \, dx \) the fraction of particles in the size range \( (x - dx)/2 \) and \( (x + dx)/2 \). The subscript \( r \) describes the type of distribution as well as the type of diameter measured. Thus when \( r = 2 \) the distribution is by area and the diameter measured is equivalent to a projected surface \( (x) \), while when \( r = 3 \) the diameter is a volume diameter \( (x) \), as determined by an electrosensing technique (Figure 5). It is, however, customary to normalize particle size distribution so that the total area of the distribution is unity, by imposing the condition shown in Equation (3)

\[
Q_r(x) = \left. \int_{x_{\text{min}}}^{x_{\text{max}}} q_r(x) \, dx \right| = 1 \tag{3}
\]

where \( x_{\text{max}} \) and \( x_{\text{min}} \) are the largest and smallest particle sizes in the distribution.

The fraction of particles in the term \( q_r(x) \, dx \) can be expressed in several ways. If the particle size measurement technique involves sieving then the graphical representation would be by weight (for constant particle density (mass/volume)) the distribution becomes one

![Figure 4 Graphical representation of particle sizes](image1)

(a) Cumulative and density distributions; (b) cumulative and density logarithmic distributions. \( \bar{q}_0, \overline{q}_1, \bar{q}_2, \bar{q}_3 \), density distribution by number, length, surface or projected area, volume or weight; \( \overline{Q}_0, \overline{Q}_1, \overline{Q}_2, \overline{Q}_3 \), cumulative distribution by number, length, surface or projected area, volume or weight; \( \bar{q}_0, \bar{q}_1, \bar{q}_2, \bar{q}_3 \), density distribution by number, length, surface or projected area, volume or weight with logarithmic abscissa. (Reproduced with permission from BSI and ISO monographs.)

![Figure 5 Statistically defined particle size distributions](image2)

Number, \( r = 0 \), length, \( r = 1 \), area, \( r = 2 \); volume or mass, \( r = 3 \).
which can be equated to a volume distribution, thus \( r = 3 \). If the particle size is measured by image analysis then the representation would be by number \( (r = 0) \) or area \( (r = 2) \). With a light-scattering particle size measurement technique an area distribution would be appropriate.

Table 7 shows the types of particle distribution that can be statistically defined (number, length, area and volume or mass) together with the terminology used to define density and cumulative distributions.

### 3.2 Particle Averages and Particle Size Distributions

To unambiguously describe the average size of the particles in an assembly or distribution of particles or powder, two statistical criteria are necessary. These criteria can be denoted by two subscripts attached to the symbol \( x \) for particle size. One subscript is related to the type of statistical distribution \( (r) \) and the other is related to the method used to calculate the average size of the particles \( (k) \) within the distribution.

The general description of an average particle size within a powder is thus dependent upon both the type of size distributions and the method of calculation from moments of the particle size mean. The moment of a distribution can be represented by the letter \( M \) qualified by two subscripts, where \( M_{k,r} \) is the complete \( k \)th moment of a \( q_r(x) \) density distribution,\(^{(37)}\) as shown in Equation (4).

\[
M_{k,r} = \int_{x_{\text{min}}}^{x_{\text{max}}} x^{k} q_r(x) \, dx \tag{4}
\]

The first subscript denotes the power of the moment and the second denotes the power of the distribution function.\(^{(38,39)}\)

This elegant nomenclature is not often used in practice. It is, however, extremely useful as it illustrates that a distribution can have an infinite number of “average” sizes.

In particle size analysis particular matter is often characterized and based on a representative sample of the powder population, and the particle size is then related to some other important physical property such as strength, flowability or solubility. A more meaningful correlation may, at times, be obtained if a specific average particle size (from the range of averages that could be obtained using moments of a distribution) is derived or calculated from the measured distribution of particle sizes, and this specific average size can then be related to a process variable. Equations for the calculation of average particle sizes or average particle diameters from a given particle size distribution are defined in ISO 9276-2\(^{(30)}\) to give a unique definition of average size, derived from the moments of a size distribution. As more than one moment can be calculated from a distribution, a range of averages can therefore be calculated from a measured particle size distribution. However, not all of these theoretically possible averages have a practical use in powder technology.

From the moments in a distribution, the average particle diameter can be expressed as \( x_{k,r} \), where \( r \) is type or quantity of the distribution (Table 7) and \( k \) is the power of the moment of size \( x \) or the \( k \)th moment of the density distribution. Several combinations of the values of \( r \) (0 to 3) and of \( k \) (3 to −3) can therefore be obtained, which shows the wealth of averages that can be calculated. Table 8 illustrates the method of calculation of averages and weighted averages and shows some of the more common averages used in powder technology industries.

### 3.3 Statistical Analytical Distribution Functions

An alternative approach to describing a particle size distribution in terms of moment averages is to fit the distribution curve into an analytical function. Some of the most commonly used functions are the Gaudin–Schuman distribution, the log-normal distribution, and the Rosin–Rammell distributions. In each case

</tbody>
</table>

\(^a\) Depending upon the chosen number of the subscript \( (k = \pm 3, \pm 2, \pm 1, 0, 1, 2, 3 \) and \( r = 0, 1, 2, 3 \) \) different average particle diameters can exist. The arithmetic mean particle diameters are, however, always based on a number density distribution, so \( r = 0 \).

\(^b\) Recommended arithmetic average particle diameters are \( x_{3,0} \) for arithmetic average length, \( x_{2,0} \) for arithmetic average surface area, \( x_{1,0} \) for arithmetic average volume.

\(^c\) \( k \) is the power of the dimension used to characterize or measure the particle size, \( x \), which can be a volume \((x^3)\), a surface area \((x^2)\), a length \((x^1)\), a number \((x^0)\), a reciprocal length \((x^{-1})\), a reciprocal surface \((x^{-2})\) or a reciprocal volume \((x^{-3})\). The recommended weighted average particle diameters are \( x_{1,0} \) from number density, \( x_{1,1} \) from length density, \( x_{1,2} \) from surface density and Sauter diameter, \( x_{1,3} \) from volume density.
the equation contains two constants, one of which is a characteristic of the particle size while the other is dependent upon the width of the size distribution. Although these functions are sometimes convenient to use, they should not be extrapolated outside the range of the actual measurements.

3.3.1 Gaudin–Schuman Distribution
The Gaudin–Schuman distribution is shown in Equation (5).

\[ Q_r(x) = Q_s(x) = \left(\frac{x}{x_{\text{max}}}\right)^m \]  

(5)

This expression is included because it is an example of a simple power law. Plotted on a logarithmic scale the distribution is a straight line. The characteristic size is that of the largest particle, \(x_{\text{max}}\). The width of the distribution or decrease of scatter is signified by the slope, \(m\). The wider the distribution, the smaller the slope.

3.3.2 Rosin–Rammler–Sperling–Bennet Distribution
The Rosin–Rammler–Sperling–Bennet distribution is shown in Equation (6).

\[ R(x) = 1 - Q_r(x) = 1 - Q_s(x) = \exp\left(-\frac{x}{\lambda}\right) \]  

(6)

This distribution is based on an exponential function and thus tends to be applicable in a process where many random events occur consecutively. It is often used to describe the products of a comminution process. The function can be plotted as a straight line on a natural log of a natural log (ln ln) versus natural log (ln) scale. By taking natural logs twice, Equation (7) is obtained

\[ \ln \ln \left(\frac{1}{R}\right) = n \ln x - n \ln x' + \ln \ln e \]  

(7)

where \(\ln e = 1\) and \(\ln \ln e = 0\).

The characteristic size \(x'\) is the size of \(x\) corresponding to a cumulative percentage \(Q_s(x)\) equal to 63.2% undersize or an oversize of 36.8%. The width of the distribution or decrease of scatter is signified by the slope, \(n\).

3.3.3 Log-normal Distribution (Gaussian/Laplace/De Moivre)
The normal distribution can be described by Equation (8).

\[ q(z) = \left(\frac{1}{\sqrt{2\pi}}\right) \exp\left(-\frac{z^2}{2}\right) \]  

(8)

This is the Gaussian normal distribution, which describes a completely random distribution of sizes around some mean. In a distribution which has a linear abscissa for particle size then \(z\) becomes equal to \((x - x_50, r)/2\) and for a logarithmic abscissa for log sizes \(z\) becomes equal to \(\ln(x/x_50, r)\). The Gaussian curve can be useful for some narrow, naturally occurring distributions. Usually, the size distributions of powders are too wide for this function, and the log-normal distribution must be used. If this distribution is applicable a plot of probability versus ln size will yield a straight line. The width of the distribution or decrease of scatter can be signified by the slope, \(s\). If the distribution has an arithmetic or normal distribution then \(s = (x_{84} - x_{50}) = (x_{50} - x_{16})\), where \(x_{84}\), \(x_{50}\) and \(x_{16}\) are the values of size at which \(Q_s(x)\) is 84%, 50% and 16%, respectively.

With a log-normal distribution \(s = \ln(x_{84}/x_{50}) = \ln(x_{50}/x_{16})\).

To obtain an evenly spaced graphical representation of a wide distribution of sizes, which will ensure the “noncrowding” of sizes together, the size axis can be changed from an arithmetic scale to a logarithmic scale. The degree of resolution of size, or space between points, is shown in Table 9. With the arithmetic scale the distance between the points decreases with an increase in particle

PARTICLE SIZE ANALYSIS: INTRODUCTION

size, while with a logarithmic scale the distance between points remains uniform.

In current particle and powder processing the required particle mixtures may be elaborate and thus far more complex than can be described by a two-parameter model. Modern computing techniques do, however, enable the easy solution of numerical equations and the computer can accept the distribution function as a series of numbers which can then be readily visualized graphically on a computer screen.

4 THE METROLOGY OF PARTICLE CHARACTERIZATION

In considering particle-measuring techniques, the first major distinction that should be made is between direct and indirect methods of measurement. If the particles can be directly observed by an optical microscope or an electron microscope then an indefinite amount of information can be obtained from the image of the particles. Frequently, there is a limitation on the number of particles that can be analyzed in a reasonable time, so image analysis techniques are usually used for more sophisticated experimental and research analyses. In principle, any physico-chemical phenomenon which is dependent upon particle size can be used to measure a particle dimension. In practice it is more convenient if the relationship between the phenomenal mechanism and the particle size is known. Currently there is a wide range of commercially available equipment, but it is based on relatively few physical principles. Nanotechnology has been used in the production of electrospray-dried biomolecules[40] and thermoelectrically and electronically configured nanofilms and nanocomposites.[41] The advent of this technique, together with concerns over the emission of nanosized particles and microsized particulate masses from low-emission diesel engines,[42] and the introduction of new legislation on air quality,[43,44] has meant that other size-dependent physical properties may have to be used for particle size characterization and incorporated into new and novel measurement systems.[45] Air pollution regulations do not apply only to the automotive industries since National Ambient Air Quality Standards are mandatory for most powder producers and users.[46]

New physical principles, such as those used in differential mobility analysis, small angle X-ray scattering and ultrafine condensation nucleus counting, may have to be considered for the future measurement of nanoparticles as well as the modification of accepted metrology to discriminate between, measured and monitored micrometer and nanometer particle sizes.

The methods that are commonly used these days for characterizing industrial powders, both off-line and in some cases on-line, are:

- sieving
- sedimentation
- electrical sensing zone techniques
- light scattering
- ultrasonic attenuation.

The first three are established off-line techniques that have been thoroughly tested and developed, and from which reproducible and replicatable results can be obtained. They are, however, less amenable to automation and on-line application. The last two techniques are at present generally off-line measurement techniques but are amenable to further technological modifications for use in automated powder processing plants.

4.1 Off-line Metrology

Off-line metrology, as seen in modern particle size instrumentation (Table 5), can be categorized as shown in the following sections.

4.1.1 Direct Dimensional Measurements

These measurements are typified by the microscopy and sieving techniques that are generally applied to particulate systems in the 10–25000 µm size range (although the maximum particle size of a powder is generally accepted to be below 1000 µm). The lower size limit can be extended to the 1 µm level for both techniques.[47] Particles undergoing size analysis by sieving have to be robust to withstand the sieve action, which can cause attrition when a “dry” sieving technique is used. For fragile particles there is a “wet” technique, in which water or organic solvents are used to support delicate materials, and when either wire or electroformed sieves are used.[48–50] The particles must be insoluble in the suspending fluid.

4.1.2 Transport Measurements

Metrology based on the transport phenomena of particles, as seen with Stokesian sedimentation and elutriation, covers a particle size range from 10⁻³ to 10⁻⁶ m (1000 µm to 1 µm) when the force causing particle settling is gravity. The sizes measured by centrifugal separation are smaller and generally in the 0.05–25 µm range (Table 5). Recently it has been argued that the lower particle size limits for gravitational sedimentation can theoretically be specified in terms of height and time of fall, rather than relying on the vague statement that the Reynolds number should be less than 0.25. The lower particle size limits for gravity
sedimentation were found to be inversely proportional to the cube root of the measurement height and inversely proportional to the fifth root of the measurement time.\(^{(51)}\) Convection currents will, however, always exist within a particulate gravitational suspension system with particle sizes of less than 1–2 µm. Thus a protracted measurement time, to achieve a supposed measurement of particles below 1 µm, tends to be suspect because of mass flow and possible temperature variations which cannot, with any degree of certainty, be measured. It is therefore essential that there is an increase in the degree of temperature control when the sizes of particles being analyzed by gravity sedimentation decrease below 50 µm.

### 4.1.3 Rapid Physical Response Measurements

Rapid response particle size analysis can be achieved with electrozone sensing, Fraunhofer diffraction and nephelometric (light scattering) techniques. In diffraction and light scattering instruments the intensity of light scattered by the particles, usually in suspension, is recorded as a function of the scattering angle. The light scattering models used to determine particle size from rapid response instruments depend on Fraunhofer diffraction, Mie theory or ray optics.\(^{(52,55)}\) The size range measured with this group of instruments, unlike the unlimited size range of the direct measurement group, tends to be between \(10^{-3}\) m (1000 µm) and \(10^{-7}\) m (0.1 µm). Colour absorbance coupled with radiation absorbency may cause some inaccuracies in photozone sensing. With light scattering instrumentation, which is dependent upon the computational models that deconvolute the measured scattered light intensities falling onto photodetectors, it is always assumed that the light scattered emanates from spherical particles. Thus either an under- or an overestimation of the finer particle sizes in a distribution may occur because of either the computer model or the insertion of incorrect particle and suspending fluid physical data into the computer program. The anomalies seen in laser light scattering instruments may at times be due to instrument misalignments, but the main source of error is due to incorrect choice and application of the computational model used for different types of particles, refractive indices or particle size distributions. The electrozone sensing technique can give size measurement distortions with highly conductive or very porous materials, because of incorrect volume displacement.

When the laser diffraction technique was first introduced, the scattering angles were less than 14°, but now instrumental technology has advanced and the ISO monographs (Table 10) have divided laser light scattering techniques into two or more categories. Low-angle laser light scattering (LALLS) instruments limit the minimum particle size that can be measured by this technique to 1 µm. The laser technique has now been broadened to capture light scattered over a much wider angular range. Other improvements include the placement of light detectors at various angles to the incident beam and the use of lasers with different wavelengths of light and polarization. Many recent instruments now have angles up to and at time greater than 150°. With the application of Mie theory\(^{(54)}\) as well as the approximate theories of Fraunhofer and anomalous diffraction,\(^{(52)}\) particle sizes down to the sub-micrometer range or less (<0.1 µm) can readily be analyzed with converging beams and more than one focusing lens. Since all the theories used are based on the scattering of light from spherical bodies, irregularly shaped particles in the nanometer size range can theoretically be measured. The measured/computed size for nonspherical particles is the equivalent sphere size, which is an equivalent cross-section generally termed the Sauter diameter (or in ISO terminology the \(x_{1.2}\) (average length-surface)) or the average volume-surface diameter.

### 4.1.4 Topography, Surface Area and Porosity

In many powder technology industries, such as pharmaceuticals, foods, ceramics and cosmetics, information on a range of different particle and powder characteristics which can be used for discriminatory tests on resources – to measure the purity of solid materials and as aids to facilitate product improvement and development – as opposed to the particle and bulk characteristics

</table>
of powders to facilitate industrial production, has always been of paramount importance.

One of the alternatives to measuring particle size and shape, and one which is becoming of more and more importance mainly because of the ease with which it can now be measured, is measuring the surface area of a powdered solid.

The ease of agglomeration and compaction, together with many other powder technological processes, can vary greatly for materials that have chemically identical structures but possess differing physical natures. Expressing the physical nature of the materials in terms of the energy, enthalpy, solubility or dissolution potential per unit surface area has thus enabled characterization in the choice of preferred raw resources. Whenever a solid is in contact with a fluid the interface between these two phases is dependent upon the surface area available to interact with the surrounding fluid, be it gaseous or liquid.

4.1.4.1 Surface Area of Powdered Material Measurement of size, shape and size distribution is generally accepted as a means of characterizing simple end-user products, but with more complex particles, surface-modified granulates and “high tech” designer multifunctional powder systems, the parameter of surface area together with inter- and intraparticulate space within aggregated, agglomerated or compacted powders can give a more meaningful explanation of particle–particle behavior. The need to control particulate structures and to modify the surface of the resultant product is thus an emerging commercial demand. The morphology of a particulate surface can either be described as rugged or tortuous as opposed to a smooth surface. Fractal geometry, from image analysis, can be used to describe not only the particles’ shape but also the texture or roughness of the agglomerated surface. Penetration into all the cracks and cannies which are generally present on the surface of a rugged particle is best accomplished by the adsorption of a fluid onto the surface of a solid.

Because of the wide use of powdered material in various fields of engineering and technology there is no unique method for analysis or characterization of the topography (surface) or the internal structure (pore/void distribution) in complex porous matrices. The surface areas of size-enlarged particles or powders are generally determined from the monolayer or multilayer adsorption region of a low-temperature nitrogen adsorption isotherm using the Brunauer–Emmett–Teller (BET) equation. The nitrogen BET method is one accepted technique for the measurement of surface areas. Another, mainly used for low-surface-area powders (<1.0 m² g⁻¹), is krypton adsorption. The protocol of surface area measurement, together with the comparison of measured surface area values of powders against standards that have been approved by the powder technology community, is therefore a necessity in global validation of powdered materials. One of the most comprehensive descriptions for the determination of surface area and porosity by physisorption has been published by the International Union of Pure and Applied Chemistry (IUPAC).

The degree of humidity is another important factor in the preparation and assessment of the mechanical properties of particles, powders, cakes and compacts. Most problems encountered in the formation and subsequent behavior of particulate material can be related to the influence of either a liquid or gaseous phase on the solid surface interface. Elbirli et al. have shown that the degree of humidity controls the extent of capillary condensation of water between points of contact between particles.

The shear strength of packed beds of rounded, spherical type particles decreases with an increase in humidity. However, with irregularly shaped, angular particles with sharp contact points an increase in the adhesive force, and thus the shear strength of a powdered bed occurs with an increase in humidity. This contradiction is dependent upon the presence of liquid rings or the onset of the funicular state between particles. These phenomena are in turn dependent upon the surface area and surface irregularities of particles. Since the presence of moisture is generally influential in either the agglomeration or disintegration and dissolution of powdered materials, investigation into the effect of moisture, by the determination of water adsorption isotherms, is one of the more important characterization techniques used to measure the specifications and properties of compressed and uncompressed aggregates, granules and agglomerates of fine particles. The specific surface area of particulate and granulate material can be calculated from the BET equation at low temperature (77 K), but at room temperature it has been found, because of the increase in the range of linearity, that it is preferable to use the Huttig equation rather than the BET equation for surface area measurements by water adsorption.

Information obtained from either nitrogen or water physisorption measurements is at times limited to the surface topographical features of the solid, but recently analysis and interpretation of nitrogen and water adsorption–desorption isotherms has been extended using the...
PARTICLE SIZE ANALYSIS: INTRODUCTION

4.1.4.2 Porosity in Particles The techniques available for the physico-chemical characterization and measurement of either intraparticulate and interparticulate space are dependent upon the magnitude of the space dimensions to be measured. The material matrix within an agglomerated or compacted mass of powder may have pores or voids that are generally in the 1.0 nm to 0.1 mm size range. These pore/void spaces can be sized by the physical adsorption of various vapors or gases at low (nitrogen, krypton and carbon dioxide) and ambient (water, butane or organic vapors) temperatures. Since the techniques chosen for the characterization of porous materials are, to some extent, dependent upon the dimensions of the space to be measured and the mechanisms of pore space filling, it is expedient to classify pore space or porosity in terms of the dimensions of the space, with the caveat that the size limits are arbitrary and can be influenced by the interactions of the solid and fluid used in the measurement technique. Pores exceeding 50 nm in width are generally termed macropores, while pores with a width not exceeding 2 nm are micropores. Pores of intermediate sizes are termed mesopores.

Mesopore Space. Although there is no single current theory of adsorption capable of providing a comprehensive mathematical description of physisorption isotherms over the entire range of relative pressures, it is possible to determine from an isotherm not only the surface area of a particulate solid, but also information on the texture, pore spaces or topography of solid materials from the multilayer and the capillary condensation regions of the isotherm. The demarcation between external and internal surface is dependent, however, on the accessibility, size and shape of the adsorbate molecules, as well as the pore space distribution in the solid. In the case of a solid which has mesoporosity, the adsorption isotherm tends to remain nearly horizontal as the relative pressure range approaches unity. The total pore volume can be evaluated in such isotherms – usually classified as type I or IV BDDT (Brunauer–Deming–Deming–Teller) isotherms – from the Gurvitsch Rule. When macropores are present the adsorption isotherm tends to rise rapidly near the relative pressure value of unity and reliable total pore volume measurements can only occur with carefully controlled experimental procedures. This type of isotherm is usually classified as a type II BDDT isotherm.

Micro pore Space. When the dimensions of the adsorbate are similar in magnitude to the capillary dimensions within solids, the filling of these spaces (micropores) at low temperature results in a type I BDDT isotherm. Type I isotherms in most cases do not show hysteresis with microporous material, although narrow hysteresis has been found with some adsorbate–adsorbent systems. Lippens et al. showed that the specific surface size and shape of micropores can be obtained from a plot of experimental adsorbed volumes at specific relative pressure versus the statistical thickness at the same relative pressure of an adsorbed layer on a nonporous solid. Unhindered formation of multilayers on nonporous surfaces produces a linear relationship, passing through the origin between the volume adsorbed and the thickness of the multilayer adsorbed on the nonporous solid, a $V_{a-t}$ curve. The slope of this line is a measure of the surface area of the porous or nonporous material. At higher relative pressures, and thus larger $t$ values and pore space dimensions, deviations from linearity can occur. At certain relative pressures more adsorbate can be adsorbed into specifically shaped and sized pores than onto a corresponding nonporous solid. A decrease in adsorption will cause a decrease in the slope of the $V_{a-t}$ relationship – the curve becoming convex to the $x$ axis – and this is indicative of microporosity. An increase in the slope of the $V_{a-t}$ equation occurs when the size of the pore space is larger or slit-shaped, and is indicative of mesoporosity.

Differentiation of the $V_{a-t}$ curve or Sing’s $\alpha_s$ plot, at known relative pressures and thus pore radii, is the basis of the micropore analysis method of Brunauer et al. It is essential, however, in the determination of micropore space distributions, that a nonporous reference solid $t$-curve be chosen which has an adsorption coefficient value similar to that of the unknown structure. Provided that the micropore size distribution is not too broad then excellent agreement between derived values of micropore volume and pore width can be obtained with Sing’s “alpha s” ($\alpha_s$) plot and the Dubin–Radushkevich equation.

4.1.4.3 Mercury Intrusion Porosimetry Determination of the pore space distribution by mercury porosimetry has, because of the relative simplicity, versatility and speed of the technique, been used for many quality control characterizations in preference to other techniques. The range of porosimeters available and discussions on the accuracy and reliability of the mercury intrusion method have been covered by Orr (van Brakel et al.) The principle of mercury pore space distribution is based on the fact that mercury does not wet most materials....
(the contact angle is greater than 90°). One of the difficulties in interpretation of mercury porosimetry results is the inability to distinguish between penetration into inter- or intraparticle space. With nonporous material only interparticle space exists, but many compressed and uncompressed particles contain intraparticle space. Critical examination of porosimetry curves may, at times, show two sharply defined regions, one at relatively low pressures and the other at higher pressures. It is thus beneficial to measure an overall pore–void size distribution over the 1 nm to ca. 50 μm range using both the adsorption and mercury penetration techniques. This then aids the recognition and discrimination of the interparticle and intraparticle spaces, especially with microporous particles.

### 4.2 In-line and In Situ Particle Characterization

Orr(79) and later Leschonski(80) described the start of a new era involving rapid-response particle–process-control sizing instruments, while Scarlett(81) highlighted the statement that Heywood(24) had made many years before: “a size analysis procedure which can form part of a fully automated production unit will be needed to feed back information to the process”.

On-line monitoring and process control does not, however, remove the problem of obtaining a representative powder sample. It only changes the essential sampling operation required to obtain a particle-process parameter from a manual laboratory collection of particles to a possibly automated particle collection process. These on-line sample collection processes, followed by size or particle characterization techniques, may have computer control, collect many more powder samples and possibly have more rapid-response times, but on-line particle characterization still does not overcome the problem of collecting, removing and transporting the particulate sample to the particle characterization instrument.

As time, effort and money can be wasted by analysis of a nonrepresentative sample, the emphasis for size measurement/characterization, with the advent of computerized information technology, has shifted from off-line batch techniques to on-line and in-line analysis. Ultimately the desired goal for many process and product engineers is in situ particle characterization and control. On-line measurements nowadays are largely devoted to modification and adaption of off-line methods.(79,83,84)

Even if the on-line analysis has a rapid response of only a few seconds or parts of a second this will eventually be superseded by in-line and/or in situ particle size and size distribution measurements.

In-line and in situ methods of characterizing particulate systems attract the attention of industry because:

1. The physical characteristics of the particles in a chemical process influence both the dynamics of the process and the final product specification.
2. In a dynamic continuous chemical process there should be a continuous dynamic measurement that can control the particle characteristics of the powdered material in terms of particle size, particle size distribution, shape, bulk density and other particle or powder characteristics.
3. Characterization of the mechanics and dynamics of the chemical process itself is also essential, initially to understand the process, then to control, improve and optimize the plant in terms of safety and cost effectiveness, and finally to tailor-design the final product from the chemical process.

Laser-based particle characterization instruments may be ideally positioned to achieve in-line or in situ particle size analysis because of the manner in which particles are detected and the ease with which computational manipulation of the collected information, needed to record a desired particle size or process parameters, can be accomplished.

### 5 SHAPE CHARACTERIZATION OF IRREGULAR PARTICLES

The need nowadays is not only for the measurement of size and size distributions, but also for the measurement of shape and shape distributions. Although Rose(86) stated in 1961 that: “perhaps one of the most abortive searches yet made is for a means of defining the shape of a particle”, many workers are now currently appraising past work on shape factors. Shape measurement, initially of academic interest only, began to find credibility when shape characteristics were incorporated into industrial and commercial powder and granulate specifications.

The complexity of shape analysis by analytical methods other than Mandelbrot(87,88) fractal analysis emphasizes the need to describe shape by more than one technique and parameter.

Most instruments for shape analysis compare the profile of an irregularly shaped geometric particle with that of a known geometric shape such as a sphere, cube or rectangle. The shape of the irregular particle is then described in terms of length and width or simply a ratio devised from computer image analysis. The main approaches to the development of techniques and instruments to characterize and measure the shape of irregularly shaped particles can be illustrated in several ways, as shown in Figure 6.(89,90)
5.1 Direct Measurement of Single Particle Shape

5.1.1 Dimensionless Geometric Shape Factors

Particle shape is a fundamental characteristic of a particle, in a manner similar to particle size. In BS 2955 \(^{(25)}\) various types of particle shape were described in words, and numerous general shapes have subsequently been defined (Table 11). These verbal descriptions are, however, inadequate for incorporation into equations and calculations to ascertain the effect of particle shape on various particle systems, particle properties or the design of bulk powder handling equipment. One of the first attempts to standardize particle shape measurement for individual particles was by measuring the length or
diameter and the breadth or width of a particle and then, from the protocol outlined in BS 512 (1966), assigning different and arbitrary ratios of particle breadth to length, \( B/L \), and particle thickness to breadth, \( T/B \), to various three-dimensional particle shapes. Regular geometric shapes, such as disks, rods, blades and equidimensional particles, could then be assigned a numerical value relating to the shape of the body or particle rather than a literal description.

Herdan\(^{13}\) had stated, before the publication of BS 512 (1966), that any “shape factor” should have a three-fold function:

1. It should be a factor of proportionality between the particle size determined by different methods of particle characterization, so that, for example, the particle size determined by microscopic techniques could be compared with that determined by sedimentation.

2. Shape factors should be conversion factors for expressing the results of different particle measurement techniques as an “equivalent sphere” parameter.

3. Shape factors should transform the second and third powers of a measured particle diameter into the parameters of particle surface area or particle volume.

The volume of a particle can thus be expressed as the volume coefficient (volume shape factor) multiplied by the cube of some characteristic dimension. Similarly, the surface area of a particle can be expressed as the surface coefficient (surface shape factor) multiplied by the square of some characteristic particle dimension.

Algebraically these definitions can be written as shown in Equations (9) and (10)

\[
V = \alpha_s a^3 \tag{9}
\]

\[
S = \alpha_s a^2 \tag{10}
\]

where \( a \) is the size characteristic of the particle and \( \alpha \) is a shape factor. Using a microscope count method, the size characteristic as a one-dimensional quantity can be either a Feret’s diameter or a projected area diameter, \( a \). As the volume and surface area values for a given particle are fixed, the numerical values of the coefficients of shape \( \alpha_s \) and \( \alpha_s \) are thus dependent on the chosen size characteristic. Subscripts to \( \alpha_s \) and \( \alpha_s \) must be used to denote the method of particle size measurement. Hence for an irregular particle whose size is described in terms of the dimensions of a projected area diameter \( a \), the geometric volume shape factor \( \alpha_s \) can be symbolized as \( \alpha_{sa} \), and the surface shape factor \( \alpha_s \) as \( \alpha_{sa} \).

Measurement of the two-dimensional quantity of area can be obtained from the projected microscopic image of the particle, while the three-dimensional quantity (volume) can be measured from either a sedimentation or an electrical sensing zone technique. The electrical sensing zone method is, however, the preferred method for particle volume measurement nowadays.

When the characteristic dimension of an irregularly shaped particle is the projected area diameter \( a \), the surface of that irregularly shaped particle can thus be symbolized as \( \alpha_{sa} a^2 \), where the subscript “\( s \)” in the shape factor \( \alpha_{sa} \) denotes a surface shape factor and the subscript “\( a \)” is related to the projected area diameter \( a \). This shape factor is multiplied by the square of the particle size measurement of the particle’s projected area diameter, \( a \), which is obtained from microscopy.

When the measured dimension is that of a sphere with the same surface area as an irregular particle then, by definition, the surface area of that sphere is equivalent to \( \pi d^2 \) or \( \pi x^2 \). Likewise, from the volume viewpoint, if the volume of an irregularly shaped particle is \( \alpha_{sa} a^3 \), with \( a \) as the diameter of the irregularly shaped particle, then the volume of a sphere with diameter \( x \) is mathematically equivalent to \( \pi x^3/6 \). The surface area and volume shape factors of spherical particles \( \alpha_s \) and \( \alpha_s \) are thus numerically equal to 3.14 (\( \pi \)) and 0.52 (\( \pi/6 \)) respectively. It has been found empirically\(^{66}\) that for irregular and nonuniformly shaped particles the ratio \( V/x^3 \), where \( V \) is the average particle volume and \( x \) is the mean particle size, remains sensibly constant for various grades of particles. It has also been found empirically that the ratio \( S/x^2 \), where \( S \) is the average particle surface area and \( x \) is the mean particle size, remains sensibly constant for different sizes of the same material. It is thus possible, at times, to speak of an average particle shape within an assembly of particles, although variations in particle shape with size have been found for some processed and powdered materials.\(^{91}\) However, such theoretical considerations, although of academic interest, had little or no application in particle processing for many years.
PARTICLE SIZE ANALYSIS: INTRODUCTION

The practical application of shape analysis was initially addressed when Davies\(^\text{92}\) stated that since particle shape information was needed to describe the behavior of particles in many industries in which particles were mixed, reacted, stored or transported, and although the main parameters still remained particle size, particle size distribution, density, and surface interactions within complex particle processes, for the purposes of clarity, particle shape should be represented by:

1. the general particle form, by an aspect ratio, a proportionality constant or a shape factor;
2. the surface topography, by roughness, angularity or roundness;
3. or a combination of the previous two categories.

Prior to Davies’ practical recognition of the value of particle shape factors within industrial processing, Heywood\(^\text{93}\) had derived an expression for the shape of a particle in terms of the general geometric form of an irregular particle from the ratio of length, \(L\), breadth, \(B\), and thickness, \(T\) (Figure 7). To separate the dimensional proportions of the particle, from the geometric shape of the particle, Heywood used the ratios of elongation, \(n\) (ratio \(L/B\)) and flatness, \(m\) (ratio \(B/T\)), together with a term defined as the equidimensional shape factor, \(a_0\).

The volume shape factor of an irregular particle, \(a_v\), could therefore be represented in part by the factor \(a_0\) and also by the ratios of the elongation and flatness ratios, \(n\) and \(m\) respectively, which characterized the influence of the dimensions of the particle on the particle shape, as shown in Equation (11).

\[
\alpha_v = \frac{a_0}{m\sqrt{n}} \quad (11)
\]

From a variety of known geometric shapes, and for irregularly shaped particles with known surface shape factors \(a_v\), Heywood\(^\text{23,94}\) deduced the relationships for particle shape as shown in Equation (12).

\[
\alpha_v = 1.57 + C \frac{a_0}{m} \frac{4/3}{n + 1} \quad (12)
\]

Combined with Equation (11), this could be written as shown in Equation (13)

\[
\alpha_v = 1.57 + C a_v^{4/3} \frac{n + 1}{m^{1/3}} \quad (13)
\]

where the shape coefficients \(a_0\) and \(C\) can be determined experimentally (Tables 12 and 13). Values of \(L\), \(B\), and \(T\) can easily be obtained using an automatic scanning microscope and software. This approach to shape recognition has been used by Church\(^\text{95}\) Dwyer et al.\(^\text{96}\) and Mandelbrot\(^\text{97}\) to obtain relationships between measured particle and linear diameters and other particle parameters, for a collection of powders.

A disadvantage of Heywood’s elongation ratio is that as an irregularly shaped particle becomes more elongated and the breadth becomes smaller, the elongation ratio tends to an infinite value. Heywood’s elongation ratio has fortunately also been defined, in different terminology, as an aspect ratio which is the ratio of the length of an irregular particle divided by the width of the particle.

PARTICLE SIZE ANALYSIS

profile at right angles to the length measurement \((L/W)\). Kaye and Clark\(^{98}\) suggested that a more acceptable and possibly more practical ratio would be the chunkiness ratio, \(W/L\) or \(B/L\), which is the reciprocal of Heywood’s elongation ratio or the aspect ratio of the irregular particle. The chunkiness ratio thus gives a numerical range from zero to unity (instead of unity to infinity), as the breadth of the irregular particle decreases with length.

To distinguish between cubes and spheres, which have linear mono-dimensional values, an alternative technique is required, which involves the comparison of an irregularly shaped particle with a more symmetrical body. To these ends, comparison of the degree of asymmetry of an irregular shaped particle with that of a symmetrical body was proposed by Wadell for petrological and geological powdered soil samples. Wadell\(^{99 – 101}\) defined the shape of an irregularly shaped particle as having either sphericity, \(\psi\), or roundness, \(P\). Sphericity was defined as the ratio of the surface area of a sphere that has the same volume as an irregular particle, to the actual surface area of the irregular particle. This can be expressed algebraically as shown in Equation (14)

\[
\psi = \frac{\pi d_c^2}{\pi d_c^2} \quad (14)
\]

but can also be expressed in a more practical manner as the working formula shown in Equation (15).

\[
\psi = \frac{d_c}{D_c} \quad (15)
\]

Wadell’s roundness factor can be used to distinguish between the form of the particle and the roundness or surface perimeter, sometimes termed the roughness, of a particle. Thus Wadell’s roundness ratio is at the moment, favored instead of Wadell’s sphericity. This is because of the insensitivity of Wadell’s sphericity ratio, which requires large changes in relative particle proportional dimensions of length and breadth to thickness in order to produce significant changes in Wadell’s sphericity, \(\psi\) (Table 14).

Any shape factor that attempts to visualize and enumerate the inherent roughness of the surface of most real powdered materials is dependent on the measured fineness or surface area of particles, because the evaluation of the surface area or perimeter of an irregularly shaped particle changes in accordance with the measurement technique used to characterize an assembly of irregularly shaped particles. This can be illustrated by the sphericity value of a porous spherical

\[
\psi = 4.38 \frac{\alpha_0^{2/3}}{\alpha_s} \quad (16)
\]

Wadell’s roundness can be obtained by measuring the radius of curvature \((r)\) of each projection in the perimeter of an irregular particle. The sum of these radii can then be related to the radius of the maximum inscribed circle \((R)\) by Equation (17)

\[
P = \sum \frac{r/R}{N} \quad (17)
\]

where \(N\) is the number of projections measured (Figure 8). As the corners of a particle are worn down, the radius of curvature, \(r\), tends to \(R\) and thus \(P\) tends to unity.
particle, which is relatively low in numerical value and may therefore be indistinguishable from the sphericity of a smooth but irregular and highly convoluted particle. The area and perimeter of an irregular particle were used by Hausner,\(^{103}\) who encompassed the complicated irregular shape of a particle image within a rectangle. The dimensional characteristics measured are the side lengths of the rectangle, \(a\) and \(b\), the projected area of the particle’s image, \(A\), and the circumference of this area, \(C\). Since the cross-sectional area and circumference of a spherical particle are \(A = d^2 \pi / 4\) and \(C = d \pi\), respectively, the relationship \(C^2 = 4\pi A\) exists. Therefore for a spherical particle, which gives the minimum surface area for a given volume, a Hausner shape factor can be defined as shown in Equation (18), and has a value of unity for a spherical particle.

\[
Z = \frac{C^2}{12.6A} \tag{18}
\]

Since automatic image analyzers with appropriate computer software can now rapidly measure particle surface area (with and without porosity), perimeter, Feret’s diameter, longest chord length and number of particles (Figure 3), numerical values of the various shapes and forms of irregular particles can now be readily obtained from ratios of these various image parameters.\(^{95, 96}\)

### 5.1.2 Signature Waveforms of Irregular Particles

With the advent and development of automated microscope systems linked into and coupled with computers, the description of irregular particle shapes and the characterization of profiles by complex mathematical functions has now become available. Schwartz and Shane\(^{104}\) were the first to describe a two-dimensional profile of an irregularly shaped particle by a geometric signature waveform that could undergo Fourier analysis.\(^{105}\) The signature waveform was generated by locating, at a central position within the particle profile, a vector that touched the outline profile of the particle. The magnitude of the vector, at various angles when moved around the irregular profile, could either produce a graph of magnitude against angle or be treated as a continuous periodic harmonic waveform (Figure 6). The complex particle signature waveform could then be broken down by Fourier analysis\(^{105–107}\) into a list that commonly used the first five harmonics in a Fourier series of the simple harmonic wave to uniquely characterize the shape of the irregular particles. A list of the Fourier harmonic series within the complex signature waveform gave a dimensionless shape description of the particle. The central location of the vector could be the center of the smallest circle inscribing the particle, as in the work of Schwartz and Shane, or could be at the center of gravity of the particle.\(^{108, 109}\) The higher harmonics (>5) were believed to give an indication of the texture of the irregular particle. Kaye\(^{110}\) reviewed the work on Fourier shape analysis and found that the geometric signature method was, in reality, only of use for relatively rounded materials, such as geological fluvial sediments and spray-condensed metals or spray-dried products. Kaye, following the work of Austin et al.,\(^{111}\) used the signature waveform methodology in combination with slip-chord analysis to separate the edges of an irregular particle image and therefore introduced a new concept to the armory of shape analysis. This concept, which is termed the angular facet signature waveform, is now used in the shape characterization of abrasives and comminuted materials.\(^{113}\)

#### 5.1.3 Fractal Geometry of Rugged Irregular Particles

Mandelbrot\(^{87}\) used fractal geometry to describe the ability of a convoluted line to fill two-dimensional space. A straight line, on a flat piece of paper, without any “ups and downs” and without “wiggles” has a topological dimension of unity. As the “straight” line becomes more irregular in shape, wiggles up and down on the flat piece of paper, and has an “irregular wavelike” form, it occupies more two-dimensional space than a straight line. The fractal dimension thus becomes greater than one because of this irregular waveform or ruggedness of the line (Figure 6). The extended irregularities of the boundary of an irregular particle can be likened to a convoluted line and fractal geometry. The fractal dimension of the boundary of irregularly shaped profiles can thus be applied, as an alternative mathematical method, to obtain an index of ruggedness or texture of irregularly shaped particles. The length of a convoluted curve can be estimated from the number of steps required to traverse a convoluted curve. As the step size decreases, the zig-zag stepped curve follows the convoluted curve being measured more closely, until eventually a constant value for the length of the convoluted curve is reached (Figure 9).

Mandelbrot\(^{97}\) showed that for a fractal curve a plot of the logarithm of the estimated length of a convoluted curve against the logarithm of the step size used gave a linear relationship which extrapolated to an infinite length. The slope of the log–log plot gives a quantity \((1 - D)\) which is defined as the fractal dimension of the rugged boundary curve of an irregular particle. The Mandelbrot fractal dimension is termed a fractal which has a number between 1 and 2 and which can be used to describe the structure or shape of an irregular profile. Flook\(^{113}\) used fractal dimensions to characterize the texture and structure of geometrically constructed model particles and the profiles of carbon black aggregates. He found that for carbon black aggregates the plot of
70.5 µm diameter of 105 µm may have a diameter of 75 µm. BS 4359 Part 3 (1970), Appendix B tabulates the factor of proportionality between the particle sizes can therefore be advantageous in shape recognition, zone technique. The difference between the measured by sieve analysis, sedimentation and an electrical sensing zone technique. An irregular particle will dimension is dependent upon the physical criterion used to characterize the textured and structured profiles of a wide variety of materials.

5.2 Indirect Measurement of Particle Shape

5.2.1 Off-line Shape Characterization

One of the inherent restrictions in the characterization of particle size is that the measurement of a particle dimension is dependent upon the physical criterion used in the measurement technique. An irregular particle will be found to have different diameters when characterized by sieve analysis, sedimentation and an electrical sensing zone technique. The difference between the measured sizes can therefore be advantageous in shape recognition, and the factor of proportionality between the particle sizes determined by different analysis techniques can be regarded as a shape factor. BS 3406 Parts 2, 3, and 4 (1963) states that a particle found by sieve analysis to have a diameter of 75 µm may have a mean projected diameter of 105 µm or a mean Stokes diameter of 70.5 µm. BS 4359 Part 3 (1970), Appendix B tabulates calculated and experimental values of surface, volume and specific-surface coefficients (shape factors) for various dimensional forms and irregular particle shapes. These shape factors were obtained from sieving, permeability, sedimentation, electrical sensing zone and light extinction methods of particle size and surface area measurements. In all cases the numerical values of 3.14, 0.52 and 6.0 for αsv, αsv, and αsv, respectively, applicable to nonspherical or irregularly shaped particles over a range of sizes from 2000 µm to 0.5 µm.

From Heywood’s (93) flatness ratio \(m = B/T\) and elongation ratio \(n = L/B\), a relationship between the shape and sieve characteristics of a powder can be established, as shown in Equation (19)

\[
x_a = 0.98 \left\{ \frac{2m^2}{m^2 + 1} \right\} x_t
\]

where \(x_a\) and \(x_t\) are the projected area and sieve diameter respectively for various values of \(m\) and \(n\).

Nyström and Stanley-Wood (114,115) described a ring gap sizer, initially used for the characterization of fragile explosive materials, which could measure uniquely the thickness of particles, as opposed to an intermediate diameter between length and thickness as obtained by sieve classification. The geometric mean particle size obtained from the ring gap sizer was within 7% of the mean thickness of particles measured by microscopy. Comparison between the ring gap sizer diameter and the dry sieve diameter could thus be used to establish shape factors of free-flowing materials.

Pilpel (116) showed that the shape of small particles obtained by comminution is dependent upon the method of size reduction. Micronized pigments are often less irregular and more spherical in shape than particles which have been repeatedly fractured and sheared by attrition. Table 15 shows the shape factors for several micronized or fractured materials. As the shape factor – the ratio of the calculated surface area obtained from electron microscopy to the BET measured surface area – approaches unity, it indicates a particle with a more spherical form. The effect of size and shape on the flow and failure properties of penicillin powders, which have an angular prismatic form, was shown by Walton and Pilpel (118) to affect the bulk powder characteristics of cohesion, tensile strength, internal friction and failure factors.

5.2.2 On-line Shape Characterization

In-line and on-line techniques for product engineering and the characterization of industrial powder processes continue to attract the attention and demands of industry because particles passing through any physico-chemical
process affect the performance of the process and the specification of the product. For most operations the two most important parameters in process monitoring and control are particle size and morphology. With recent advances in sensor technology it is now possible to implement both size measurement and shape morphology characterization simultaneously. This can be done using two separate units, one for size and the other for shape, or a single unit which can, by laser light illumination, produce both a particle size distribution from a flowing stream of particles, using a time-of-flight (TOF) or time-of-transition (TOT) technique, and also a morphological particle shape characteristic.

Although light-scattering techniques are not commonly used for particle shape classification there is, within the scattering signature from the scattered light intensities obtained from the particle size distribution, encoded information from which it should be possible to infer the shape of particles. By changing the geometric shape of the photodetectors from a series of semicircular concentric detectors to an array of wedge-shaped detectors in a segmented ring, the shape of particles may be measured.

To record the particle shape information from the scattered light, the classical laser diffraction detection system (which uses semi-ring-shaped detectors to collect the radial spatial frequencies or intensities of the particle field), has to be changed to include wedge-shaped photodetectors which collect encoded particle shape information in the form of azimuthal spatial intensity frequencies. The influence of shape on size measurement by light blockage and the characterization of plate-like particles has been appraised for rapid response instrumention and in modified on-line light techniques.

It is now currently accepted that a combination of both size and shape measurements will lead the way forward to the characterization of mixed particle species, complex designed particles and multifunctional agglomerated systems of varied size, shape, and mix.

### 6 NATIONAL AND INTERNATIONAL STANDARDS AND REFERENCE MATERIALS

#### 6.1 National and International Standards

For the purpose of scientific communication, and to avoid disputes in commerce, industry and legislation, it has long been recognized that great value can be derived from using measurements directly related to fundamental standards. Most physical, physico-chemical and chemical primary and fundamental units have been defined by scientific experts, and are maintained under specific conditions that permit little or no variation in the value of the unit. In the field of powder technology, with the proliferation of particle size measurement techniques, there are several ways that an irregularly shaped mass of material can be characterized and sized. The method generally used at present is known as the equivalent sphere diameter, but more complex particle parameters may be used in the future as advances occur in the in situ recognition of assemblies of particles within industrial particle processing operations. It may be beneficial one day to characterize particulate matter obtained from a production process in terms of the purpose for which the particle or powder has been produced rather than to undertake the arduous task of sizing. Scarlett and Leschonski both appraised the necessity to size particles using equivalent sphere diameters. The characterization and sizing of particles in industries dealing with powdered material is generally only used to specify and maintain product functionality, and not to generate products of a certain size. As long as the product functionality (be it flowability, solubility, taste or drug efficacy) is maintained within specifications, then size is a secondary parameter. With the diversity of particle-sizing techniques readily available it may therefore be advantageous to measure the appropriate size of the particle using a physical property as closely related to the product functionality property as possible. There is therefore a need to calibrate powder measurement techniques to measure reconcilable particle properties closely related to the product properties, which at the present time happens to be the reconcilable property of size. Reference materials are then required, together with the careful standardization of a few basic techniques, to achieve confident particle sizing.

Leschonski has commented that the measurement of size and size distribution of irregularly shaped particles ranging from a tenth of a micrometer to
several centimeters is, and presumably always will be, a difficult task. Whichever method is used for particle size measurement, there are two prerequisites which have to be accepted by all powder analysts because of the truisms of powder technology. The first prerequisite is that whichever particle size measurement technique is selected there has to be a recognized and a commonly accepted protocol or procedure, and therefore ultimately an agreed national or international standardized technique, to determine the particle size metrology and to ensure that one analyst’s results will tally with another analyst’s results. Confidence in the measurement technique chosen and the instrument used, from the simplest to the most sophisticated, is enhanced when the measurement can be related to a recognizable standard. Traceability may not be essential for the simplest in-house routine quality control tests, provided that the instrument is verified to give consistent results in terms of reproducibility with a selected standard or possibly a certified material.

This consensual standard method of analysis need not give an absolute measure of size, but any technique of size measurement should (and ultimately legislation may make this mandatory) be based on measurements where all the physical criteria measured are traceable directly to the international standards of mass, length and time and not derived from a second-order effect, unless the alternative measurement technique has been calibrated by certified reference materials and therefore becomes a traceable secondary standard. The second prerequisite is to have available reference materials (section 6.2), which in the special case of powder technologists tend to be reference powders of known particle size and particle size distribution. These reference powders can then aid the verification of the first prerequisite.

Standardization of the measuring methods available to the powder technologist is becoming, because of the global advances in powder manufacturing and chemical processing, more and more international rather than national. However, a situation may arise where a more sophisticated national standard may be created by an advanced technological nation, but not accepted at an international level by other less technologically advanced nations. Nowadays national standards are being harmonized within the framework of the European Community and also at an international level. National standard organizations still update current standards and tend to initiate new working standards as the processes of powder handling, characterization and particle measurement undergo innovation. Table 16 lists some of the standardization institutes that actively promote drafts and renew existing standards for the powder technological community, while Table 17 gives details of the current published British and German standards relevant to powder technology.

Many national standards are, at present, rapidly being superseded at an international level. The ISO has established a technical committee (TC 24) to standardize equipment and methods used in the size classification of particulate materials in solid or liquid states. TC 24 is divided into several subcommittees interested in test sieves, test sieving (SC 1); industrial wire screens (SC 3); and sizing by methods other than sieving (SC 4).

The work groups (WG) within SC 4 are listed in Table 10. It can be seen from the titles of the work groups that the SC 4 group has a very large remit, with the responsibility of attempting to standardize a wide range of particle size, powder surface area and powdered material porosity measurement techniques. Some of the standardization committees working in the field of powder technology are also listed in Table 10. The members of TC 24/SC 4 are Australia, Belgium, China, Finland, France, Germany, Israel, Japan, Norway, Sweden, The Netherlands, the UK and the USA, who nominate delegates to work in various powder technological fields. Table 10 also shows some of the approved and published standards together with the progress of other work groups within TC 24/SC 4.

#### 6.2 Reference Materials

In all particle size instruments available at present, except microscopes, an assessment is made of particle size distribution by recording values of a size-dependent physical property analogous to particle size. While this is not ideal it has long been accepted that if the limitations can be assessed by users and recipients of the data obtained

from the range of size-dependent physical criteria used in present day instruments, and possible measurement techniques of the future, then a nonabsolute size measurement of irregularly shaped particles is justifiable. It is thus incumbent upon designers, vendors and users of instruments to identify the assumptions made in relating the results obtained from any instrumentation to the fundamental units of length, mass or time, or other mathematically derived or correlated units. The mechanism by which the above relationship is achieved within the instrument is known as calibration.\(^{25}\)

Leschonski, foreseeing the need for instrument calibration in terms of size and the measurement of reference materials of known size certified on the basis of traceability, advocated that the most desirable approach to describe size would be that of the volume or, if the density of the material is accurately known, the mass of the particle or particles. This has resulted in the certification, by BCR, of irregularly shaped solids (quartz) over a range of distributed sizes using the off-line techniques of sieving (160–630\(\mu\)m) and sedimentation (0.35–90\(\mu\)m) and a range of nitrogen BET specific surface area reference materials.\(^{128}\) Certified mono-sized polymer microspheres in discrete sizes from 20 nm to 2000\(\mu\)m are also commercially available from BCR and NIST.

### 6.2.1 Calibration and Traceability

Calibration can take many forms depending upon the nature of the measurements being made. In microscopy a graticule is examined concurrently with a stage micrometer that has been graduated in authenticated linear units, traceable to primary standards, by a verified standard procedure. Providing that the conditions of examination are unchanged, the graticule can then be used to make “absolute” measurements on the images of objects of unknown size.

In some other particle sizing instrumentation, spherical latex particles of known and verified uniform size can be used, so that the results produced by instruments such as laser light scattering and electrozone sensing instruments coincide with the verified values. Calibration materials or calibrants used with such instrumentation tend to consist of populations of particles whose distributions have been determined by a method that has been traceably calibrated and validated. The efficacy of a spherical calibration procedure is shape sensitive. Since a large percentage of calibration methods depend upon spherical calibrants, few problems are likely to arise if unknown test samples comprising only spherical particles are analyzed. However, since only a small percentage of industrial powdered samples exclusively consist of spherical particles a judgment has to be made as to the acceptability of the calibration in relation to the shape, or more likely shapes, present in the samples analyzed.

Whenever a device is calibrated by a user or a manufacturer it should be calibrated using suitable internationally certified reference standards, or secondary standards which are directly traceable to those international standards. For good laboratory practice, the whole measurement and calibration process must also be validated. This requires that objective evidence is established to show that the measurement process consistently produces results to within required specifications, with consideration being given to all procedural and analytical variations. When certified material that has a traceable source and pedigree is presented to another instrument that does not have the same physical basis of particle size measurement or the same size-dependent physical property, then a comparison is taking place and the certified material is acting as a reference material (Table 18).

However, if the certified material is used to adjust the output of the instrument to the values consensually accepted from the material then the instrument has been calibrated. A reference material may be used for the calibration and checking of any instrument used for particle sizing, but certified material is usually only certified for one or two fundamental methods. Care must be taken in calibrating and checking other particle sizing instruments that do not use the same physical principles as those upon which the certified material was certified. In general, materials that have a particle size distribution tend to be regarded as reference materials, while mono-sized materials tend to be used to calibrate instruments. Traceable calibrants and control reference materials (Tables 19 and 20) are available from, for example, BCR. Evidence of traceability must always be supported by a trail of documentation.

### 6.2.2 Validation and Verification

It is likely that all particle-sizing instruments will require both the traceable calibrant and the reference material approaches, in which different proportions of a series of mono-sized particulate material are mixed together to assess the parameters of reproducibility, repeatability, accuracy and possibly sensitivity of the instrument.

The validity of the software that nowadays governs and controls many particle sizing instruments will also have to be addressed, so that there is now a need to have three levels to test particle-sizing instruments:

1. verification of the software routines used to interpret the measured size-dependent physical criterion used to size irregular particles;
2. physical tests to ascertain the correctness of the size-dependent physical criterion measured with traceability;

3. certified powdered materials with known sizes and size distributions to verify and confirm that the particles displayed by the instrument are in reality the physical particle sizes introduced into the instrument.

One way of providing confidence and acceptability in the particle sizes measured from the diverse range of particle size instruments available is by verification, which can be defined as: “the examination and provision of objective documentary evidence that specified requirements have been fulfilled”. If the verification can be extended to demonstrate that an instrument or process is suitable for fulfilling the requirement of a specific intended use, then that instrument or process is said to be validated.

**LIST OF SYMBOLS**

- \( A \) Projected area of an irregularly shaped particle image
- \( B \) Breadth of an irregularly shaped particle
- \( C \) Sampling constant, which is a function of a material’s properties and which can be determined
- \( C' \) Shape constant which can be determined experimentally (section 5.1)
- \( C_0 \) Circumference of the projected area of a particle’s image
- \( d \) Size of square mesh sieve to retain 5% of the particles or a specified percentage of a specified size range of particles
- \( d_d \) Drag diameter of an irregularly shaped particle
- \( d_l \) Free-fall diameter of an irregularly shaped particle
- \( d_s \) Equivalent surface area diameter for an irregularly shaped particle
- \( d_{5t} \) Stokes diameter of an irregularly shaped particle
- \( d_t \) Sieve size diameter of an irregularly shaped particle
- \( d_v \) Equivalent volume area diameter of an irregularly shaped particle
- \( k \) Power of the moment of particle size \( x \) or the \( k \)th moment of a density distribution, which is related to the method used to calculate the average size of the particle within the distribution
- \( L \) Length of an irregularly shaped particle
- \( m \) Sample weight used in sampling (section 2.2)
- \( m \) Heywood’s flatness ratio (ratio \( B/T \))
PARTICLE SIZE ANALYSIS

\( m \quad \) Slope of the Gaudin–Schuman distribution (section 3.3.1)
\( M \quad \) Moment of a distribution
\( n \quad \) Heywood's elongation ratio (ratio \( L/B \))
\( n \quad \) Slope of the Rosin–Rammler–Sperling–Bennet distribution (section 3.3.2)
\( N \quad \) Number of projections measured in Wadell's roundness
\( P \quad \) Wadell's roundness
\( q \quad \) Particle density distribution
\( q_r(x) \quad \) Cumulative particle density distribution
\( r \quad \) Rosin–Rammler–Sperling–Bennet distribution
\( R(x) \quad \) Quantity of a particle distribution or type of statistical distribution
\( s^2(FE) \quad \) Variance of fundamental error of \((a_s - a_b)/a_b\), where \(a_s\) and \(a_b\) are content values of sample and bulk batch respectively.
\( S \quad \) Average particle surface area
\( T \quad \) Thickness of an irregularly shaped particle
\( V \quad \) Average volume of an irregularly shaped particle
\( V_{a-t} \quad \) Curve Linear relationship, passing through the origin, between the volume adsorbed \((V_a)\) and the thickness of the multilayer adsorbed on the nonporous solid \((t)\)
\( x \quad \) Size characteristic of an irregularly shaped particle
\( x_{a}, x_{1} \quad \) Projected area and sieve diameter of an irregularly shaped particle
\( x_{k,t} \quad \) Average particle size/diameter
\( x_{\text{max}}, x_{\text{min}} \quad \) Largest and smallest particle sizes in a distribution
\( x_n \quad \) Equivalent mesh diameter
\( x_s \quad \) Equivalent surface diameter
\( x_v \quad \) Equivalent volume diameter
\( x_w \quad \) Equivalent settling diameter at either high or low Reynolds numbers
\( x' \quad \) Particle size of \( x \) corresponding to a cumulative percentage \( Q_r(x) \) equal to an undersize of 63.2% or an oversize of 36.8%
\( x_{1,2} \quad \) Average length-surface or average volume-surface diameter of an irregularly shaped particle
\( x_{5d}, x_{50}, x_{16} \quad \) Values of size at which \( Q_r(x) \) is 84%, 50% and 16% respectively
\( z \quad \) Z Hausner shape factor
\( (1 - D) \quad \) The fractal dimension of the rugged boundary curve of an irregular particle
\( \alpha \quad \) Shape factor
\( \alpha_0 \quad \) Equidimensional shape factor
\( \alpha_s \quad \) Sign's 'alpha s' plot
\( \alpha_r, \alpha_v \quad \) Shape factors which denote the method of particle size measurement
\( \alpha_v \quad \) Volume shape factor of an irregular particle
\( \psi \quad \) Wadell's sphericity shape factor

Millions of tons per year of submicron particles are produced in industrial processes around the world. They are also referred to as nanoparticles, colloids, latices, polymer dispersions, mini-emulsions or micro-emulsions. These solid or liquid particles, which are mostly dispersed in an aqueous medium, have a diameter \( D \) in the \( 10 < D < 3000 \) nm range. They are used as dyes and pigments, in paints, adhesives and coatings applied to paper, as impact modifiers in plastics, as catalysts, in cosmetic and photographic emulsions, metal sols and electrodeposition coatings applied to automobiles, as excipients for pharmaceuticals, etc.

Most of the valuable practical properties of these nanoparticle dispersions/emulsions result from their extremely small size and their high specific surface area. This implies that it is essential to be able to control and measure the particle size in order to produce nanoparticle systems of consistent quality. The particle size distribution is just as important as the average particle diameter. The practical consequences of changing from a very narrow to a very broad particle size distribution with the same average diameter can be quite dramatic in many applications. For example, the viscosity of a high-solid polymer latex will decrease, the impact strength of plastic material will increase, surfaces coated with emulsion paints will become more level, etc.

Many methods, such as light scattering, electron microscopy, field flow fractionation (FFF), capillary hydrodynamic chromatography and ultracentrifugation, are used to measure the average particle diameters and overall particle size distribution of nanoparticles. Analytical ultracentrifugation (AUC) is the most versatile method with the broadest diameter range \( (1–5000 \) nm) and the highest resolution. The nanoparticles are forced to move through a predominantly aqueous medium inside an AUC measuring cell under a centrifugal force of \( 500–500,000 \) g (rotor speed 100–60,000 rpm). Sedimentation causes fractionation to take place, because the larger particles move faster. The sedimentation velocities \( s_i \) of the different fractions are measured with refractive index, ultraviolet (UV)-absorption or light scattering/turbidity detectors. The diameters \( D_i \) of the different fractions can be calculated from the difference in \( s_i \), i.e. the complete particle size distribution, according to Stokes’ law. The resolution of the AUC method is so high because, according to Stokes, \( s_i \) is proportional to the square of \( D_i \). The AUC particle size distribution method can give spurious results if \( D \) is too high, i.e. if the particles form a sediment too quickly or if they display a broad chemical heterogeneity (i.e. no uniform particle density).

### 1 INTRODUCTION

Submicron or nanoparticles with diameters in the \( 10 < D < 3000 \) nm range are produced and consumed in large quantities around the world, mostly in the form of aqueous dispersions or emulsions. Important applications for polymer dispersions (latices) are in paints, papermaking and adhesives, for modifying the impact strength of plastics and in the production of synthetic rubber. Their particle size distribution is one of their most important characteristics, because it affects many of their practical properties. Many different techniques have been developed to measure particle size distribution, such as light scattering, hydrodynamic chromatography, electron microscopy, sedimentation and FFF and AUC. The AUC method is the most versatile, high-resolution, relatively fast technique,\(^{(1)}\) and it also covers the greatest diameter range \( (1 < D < 5000 \) nm)\. The three AUC methods are described in this paper.

1. standard particle size distribution,
2. \( \text{H}_2\text{O}/\text{D}_2\text{O} \) sedimentation analysis (which is also used to measure particle densities)
3. the coupling method (which is used to measure extremely broad particle size distributions).
All three methods are based on Stokes’ equation and on Mie’s light scattering theory, which means that light scattering takes place inside the AUC apparatus. After briefly recounting the history of the AUC method, we will go on to look at the experimental set-up with an eight-cell rotor and multiplexer and its physical principles, $H_2O/D_2O$ sedimentation analysis and the coupling particle size distribution method with the aid of some illustrative examples. We will then consider future prospects by looking at a new two-laser-beam technique and AUC particle size distribution measurements of extremely small inorganic colloids (1–20 nm) with angstrom resolution, using very high rotor speeds and refractive index or absorption optics detectors.

2 HISTORY OF ULTRACENTRIFUGATION PARTICLE SIZE ANALYSIS

The first AUC particle size distribution measurements on colloidal particles were performed in 1924 by Rinde and Svedberg,\(^2\)\(^3\) (Svedberg invented AUC, and was awarded the 1926 Nobel Prize in Chemistry for his work.) They analyzed gold sols, measured their sedimentation velocity $s$, and used the results to calculate the diameter $D$ of the gold particles using Stokes’ law. Nichols, Kraemer and Bailey\(^4\) later improved the initial AUC particle size distribution set-up. Cantow\(^5\) was the first to measure polymer dispersions with a turbidity detector inside the AUC apparatus, using Mie’s light scattering theory\(^6\) of spherical-shaped colloidal particles to calculate the correct mass percentages $m_i$ of the different particle fractions. Later, Scholtan and Lange\(^7\) developed another, very simple AUC particle size distribution set-up which employed a small one-beam turbidity/light scattering detector. This set-up was further developed by Mächtle,\(^8\) who introduced the following new features: (1) a change from a single-beam to a double-beam technique; (2) an increase in the measuring capacity by a factor of seven by the introduction of an eight-cell rotor and a multiplexer, which allows simultaneous measurement of seven samples and a reference cell; (3) a modification from the common operation mode using a constant rotor speed $N$ to a new time-dependent operation mode $N(t)$ in which the rotor speed is increased exponentially during each run from $N = 0$ to the maximum speed $N = 40\,000$ rpm within 1 h, always at the same rate. This allows samples containing very small particles of about 10 nm and very large particles of about 3000 nm to be measured in the same run. The multiplexer and $N(t)$ technique were prerequisites for $H_2O/D_2O$ sedimentation analysis\(^8\) and the coupling particle size distribution method.\(^9\),\(^10\) Our latest development,\(^11\) the introduction of a parallel two-laser-beam set-up, has increased the resolution and the accuracy of AUC particle size distribution measurements. Extremely small inorganic colloids in the 1–20 nm range have become a new issue over the last three years. Their light scattering is so weak that the turbidity/light scattering detector inside the AUC apparatus cannot be used. Instead modern UV scanners or refractive index detectors (schlieren or interference optics) and constant high rotor speeds are used, as for dissolved macromolecules.\(^12\)

3 EXPERIMENTAL SET-UP

The photograph in Figure 1 shows our AUC set-up outside the rotor chamber. It includes eight measuring cells, an eight-cell rotor and a U-shaped stage, with the laser diode light source above the rotor and a fast photo diode light detector below the rotor. This set-up also contains a preparative ultracentrifuge (Optima XL, Beckman-Coulter, Palo Alto, CA, USA) which we have modified into an analytical ultracentrifuge by installing an analytical eight-cell rotor (Beckman type AN-50 Ti) and simple turbidity/light scattering optics. We have two versions of this turbidity detector, an older one with an incandescent lamp and a photomultiplier as the light source and light-receiving detector, and a newer one with a 670 nm red light laser diode and a very fast photo diode.

Figure 1 Laser optical set-up showing rotor and cells, with a laser diode above the rotor, and a photo diode below the rotor.
(see Figure 1). An AUC measuring cell is situated to the right-hand-side of this eight-cell rotor in Figure 1. The centre piece has a thickness of 3 mm and a sector-shaped cut-out. A flat glass window fitted with a gasket is placed on either side and the gap is filled with the nanoparticle dispersion/emulsion to be analyzed by injecting it through a small hole using a syringe.

A schematic diagram of our set-up is shown in Figure 2(a). The turbid dispersion to be analyzed is diluted to about 1 g L\(^{-1}\) and placed into the centre section of the 3-mm cell. The lower quartz window of the cell is covered by an apertured stop, in the centre of which is a 0.2-mm wide slit that is arranged perpendicular to the radius of the rotor. The slit picks out a beam from the entering monochromatic light.

The intensity \(I\) of this beam, which is reduced by light scattering of the latex particles according to Mie’s theory, is registered by the photomultiplier and recorded as a function of the time of travel \(t\). The concentration of the dispersions is selected so as to yield an initial light intensity \(I_0\) of approximately 10\% of \(I_{DM}\), the intensity of the pure dispersant. In our newer version, we use a 0.2-mm laser beam, no apertured stop, and a fast photo diode as the light detector.

In a monodisperse latex, all of the particles settle out with exactly the same velocity. This causes the broken one-step curve shown in Figure 2(b) to be obtained, because the intensity jumps from \(I_0\) to \(I_{DM}\) at the moment when the sharply defined, sedimenting latex front passes the measuring slit (or the laser beam). The diameter \(D\) of the monodisperse particles can be calculated from the measured jump time \(t\) by means of Stokes’ law.

In the event of a latex having a broad particle size distribution, the particles are fractionated within the sedimenting latex front according to their size, but the latex front now is blurred by large particles running ahead and small particles lagging behind. This gives a broad continuous transition from \(I_0\) to \(I_{DM}\) (thick line). If we approximate this transition by plotting a multiple-step curve (fine line), i.e. by superimposing many monodisperse latex fractions, the \(I(t)\) curve renders a curve for the integral particle size distribution (Figure 2c). This is obtained by calculating (a) the diameters \(D_i\) of the different fractions from their time of travel \(t_i\), by means of Stokes’ law, and (b) their mass fractions \(m_i\) from the respective light intensity steps \(\Delta I\) by means of Mie’s theory. The sum of all \(m_i\) values is unity. Details for calculating \(m_i\) with Mie’s theory are given in the literature\(^{8,9}\).

It should be noted that this particle size distribution analysis strictly only works for hard spheres at a standard concentration of about 1 g L\(^{-1}\) (\(\approx\) case of infinite

Figure 2 (a) Schematic diagram of the measuring set-up and (b) distribution curves. (Reproduced from Mächtle\(^{9}\) by permission of Wiley-VCH Verlag.)
dilution). For rods or soft spheres, the dependency of the sedimentation velocity on the concentration might cause errors.

The process we have developed is much more complex than the basic procedure outlined here. In fact, we measure seven samples simultaneously, employing a quasi-two-light-beam technique. A schematic diagram of our method is shown in Figure 3. The process is triggered by reference cell 0 which is filled with the pure dispersant (mostly water). The amplitude of the photomultiplier (or photo diode) impulses from measuring cells 1–7 is measured and divided by the amplitude of the impulses from the cell containing only water using a fast electronic device, then digitized for computer processing, and recorded in analog form by an eight-channel recorder (or photo diode) impulses from measuring cells 1–7 is recorded in analog form by an eight-channel recorder (for visual checks only). We no longer keep the rotor speed constant; instead, we increase it exponentially from 0 to 40 000 rpm over 1 or 2 h during each run in order to cover the smallest particles \( (D \approx 10 \text{nm}) \) as well as the largest ones \( (D \approx 5000 \text{ nm}) \). This procedure is fully automatic. The ability to measure seven cells simultaneously and to increase the rotor speed exponentially is a precondition for the two methods that will be described later, H$_2$O/D$_2$O analysis\(^{(8)}\) and the coupling particle size distribution technique.\(^{(9)}\)

4 PHYSICAL PRINCIPLES

Figure 4 shows the basic equations for the determination of both the particle diameter \( D \) and the particle density \( \rho \) by Stokes’ law. It also shows two “snapshots” of monodisperse latex particles in the cell, one of them taken at the start of the measurement \( (t = 0) \), the other one exactly at the point \( (t = t_i) \) at which the latex front passed across the measuring slit (or laser beam). A differential equation of motion can be calculated from the equilibrium of forces \( F \) acting on an arbitrary particle. The solution of the latter is Stokes’ square root equation which allows \( D_i \) to be calculated from the measured time of travel \( t_i \) or, alternatively, from the sedimentation velocity \( s_i = \ln((r_i/r)w^2t_i) \) if the particle density \( \rho_i = \rho_{PM} \) is known. An unknown \( \rho_{PM} \) can be determined by measuring the time of travel in a second dispersant of different density \( \rho_{DM} \). We employ heavy water, D$_2$O, which has a density of 1.10 g cm$^{-3}$, as the second medium. With the modified Stokes’ equation (Figure 4, bottom), \( \rho_{PM} \) can be determined simply from measured times of travel in H$_2$O and D$_2$O, and this equation is the basis of the H$_2$O/D$_2$O analysis. There are also other methods of measuring the particle density \( \rho_{PM} \): pycnometry, measurement on bulky materials, AUC density gradient techniques and the Paar density balance. It must be emphasized that the differential equation mentioned here can be solved for the case \( w = \text{constant} \) and for our new mode of operation with \( w = f(t) \). In the “classic” square root equation, \( w^2 \) changes to \( w^2 \text{ d}r \), the integral of the time of travel, which is calculated from the measured curve for \( w(t) \) using a computer.

The measurement of seven samples simultaneously is demonstrated in Figure 5. We made up a 1 g L$^{-1}$ mixture of three monodisperse Dow polystyrene calibration latices with diameters of 176, 312 and 794 nm at a ratio of 40 : 50 : 10% w/w. This mixture was filled into seven different cells and initially measured in the conventional operating mode at a constant rotor speed \( N = 4000 \text{ rpm} \). As a result, we obtained the seven full line \( I(t) \) curves. The measurement was then repeated in the new operating mode with \( N \) rising exponentially from 0 to 40 000 rpm, which generated the seven broken line \( I(t) \) curves. The respective seven three–step curves obtained in both operating modes agree well.

\[ \text{Figure 3 Schematic diagram of AUC method for determining particle size distribution, with an eight-cell rotor multiplexer set-up. (Reproduced from M"achtle\(^{(8)}\) by permission of Wiley-VCH Verlag.)} \]
CENTRIFUGATION IN PARTICLE SIZE ANALYSIS

If \( I/I_{DM} \) is plotted against \( w^2 \, dt \) instead of against \( t \) as shown in Figure 6, the seven curves obtained in the conventional operation mode (\( N = \) constant) coincide with those obtained in the new operating mode (\( 0 < N < 40,000 \) rpm). Because the latex particles are chemically homogeneous, we can convert these 14 \( I(t) \) curves into 14 particle size distribution curves. The result is shown in Figure 7, where \( m_i \) is plotted against \( D_i \). These 14 particle size distribution curves conform within 5% not only in terms of the known diameters \( D_i \) (176, 312 and 794 nm) but also in terms of the given mass portions \( m_i \) (40, 50 and 10%), thus proving that our design (seven

Figure 4 Determination of \( D \) and \( \rho \) according to Stokes’ law. (Reproduced from Mächtle by permission of Wiley-VCH Verlag.)

Figure 6 \( I(\int \omega^2 \, dt \times 10^8 \, s^{-1}) \) curves of seven mixtures of three monodisperse polystyrene calibration latices, 176:312:794 nm (40:50:10% w/w). (Reproduced from Mächtle by permission of Wiley-VCH Verlag.)

5 WATER/DEUTERIUM OXIDE SEDIMENTATION ANALYSIS

However, the method discussed in the previous section only really works if the dispersion is chemically homogeneous (with the density and refractive index of the particles being uniform). We have therefore developed a
fast H₂O/D₂O sedimentation technique to analyze non-homogeneous dispersions. As an example, Figure 8 shows the results of the H₂O/D₂O analysis of a polystyrene latex in three dispersants with different densities. The unknown highly concentrated dispersion was diluted at a ratio of approximately 1:1000 with the three dispersants H₂O (\( \rho = 1.00 \text{ g cm}^{-3} \)), D₂O (\( \rho = 1.10 \text{ g cm}^{-3} \)), and a 1:1 mixture of H₂O and D₂O, and the three corresponding \( I(t) \) curves of these diluted dispersions were measured simultaneously. The computer creates horizontal sections at intervals of 10% steps across the three \( I(t) \) curves (2% intervals are possible too). It then calculates the particle density \( \rho \) and the particle diameter \( D \) of the corresponding fraction from the respective three coupled times of travel at each point of intersection with the curve by means of the two Stokes’ equations shown in Figure 4. The table on the right-hand-side of Figure 8 shows the density distribution \( \rho \) and the particle size distribution \( D \) of the unknown dispersion. In this case, \( \rho \) is constant (1.054 g cm\(^{-3}\)). The dispersion is a chemically homogeneous polystyrene latex which is nearly monodisperse, with its diameters varying around 155 nm.

The polymer dispersion analyzed in Figure 9 is markedly bimodal. After as little as 1 h the H₂O/D₂O analysis revealed that the dispersion was a chemically homogeneous latex with a particle density of 0.89 g cm\(^{-3}\) (because the three coupled \( I(t) \) curves can be forced to coincide by linear stretching along the x-axis). It therefore

**Figure 7** AUC particle size distribution curves of seven mixtures of three monodisperse polystyrene calibration latices, 176:312:794 nm (40:50:10% w/w). (Reproduced from Mächtle\(^{81} \) by permission of Wiley-VCH Verlag.)

**Figure 8** H₂O/D₂O sedimentation analysis of a polystyrene latex (\( D = 155 \) nm). (Reproduced from Mächtle\(^{81} \) by permission of Wiley-VCH Verlag.)

**Figure 9** H₂O/D₂O sedimentation analysis of a polybutadiene latex mixture 115 nm:350 nm (72:28% w/w). The insert shows the three resulting particle size distributions of this mixture in the three media H₂O/1:1/D₂O. (Reproduced from Mächtle\(^{81} \) by permission of Wiley-VCH Verlag.)
had to be polybutadiene. The bimodality is caused by the two particle components having different diameters, 115 and 350 nm respectively. We had prepared this dispersion ourselves by mixing polybutadiene particles of diameters 115 nm and 350 nm in a ratio of 72:8% w/w. The insert in Figure 9 shows that the resulting three H2O/1 : 1/D2O particle size distributions of this mixture reproduces very well the given mixing ratio.

Figure 10 shows another example. Here the three I(t) curves of an unknown dispersion can not be forced to coincide by linear stretching along the x-axis, therefore it must be chemically inhomogeneous. Indeed we had prepared a mixture of the nearly matching 155-nm diameter polystyrene particles and the 115-nm diameter polybutadiene particles at a ratio of 12:88% w/w. Some of the values for \( p \) and \( D \) are reasonable, but some of them are physically absurd and must be disregarded (they are crossed out here). This indicates that we can confirm within 1 h whether an unknown dispersion is chemically homogeneous or inhomogeneous by means of fast H2O/D2O analysis, and we are able to decide whether or not it is possible to determine the particle size distribution by AUC. If H2O/D2O analysis states that the sample is chemically inhomogeneous, we then use the powerful AUC density gradient technique\(^8,13,14\) to analyze the inhomogeneity in the particle density in a quantitative, detailed manner.

6 COUPLING PARTICLE SIZE DISTRIBUTION TECHNIQUE

Now we will turn our attention away from monodisperse particles and to extremely broad distributed dispersions, for which we use the coupling particle size distribution technique. We prepared a sample with a broad particle size distribution by mixing ten polystyrene dispersions with a narrow distribution, having \( D_{50}\% \) diameters from 67 to 1220 nm, in equal portions of 10% w/w each as shown in Figure 11. Figure 11 also shows the \( I(t) \) curve obtained by measuring this mixture of components at the standard concentration of 0.35 g L\(^{-1}\) (solid line) which gives an initial light intensity of about 5% of \( I_{DM} \). Each component can clearly be distinguished as a single step with the exception of component 10, the smallest one. The \( I(t) \) step for the latter is tiny because of its extremely poor light scattering, i.e. it is badly resolved.

Our coupling technique can solve the problem in cases such as these. We measured the ten-component mixture simultaneously in the same AUC run at a ten-times higher concentration, i.e. at 3.5 g L\(^{-1}\). The additional \( I(t) \) curve (broken line) that we obtained shows component 10 at high resolution as well as components 9–7, while component 6 can be partially seen. Components 1–5 cannot be seen because their measuring signal is zero. These two \( I(t) \) curves can now be coupled mathematically at the two marked points by combining the lower section of the 0.35 g L\(^{-1}\) curve with the upper section of the 3.5 g L\(^{-1}\) curve (see Mächtle\(^9\) for details).

If we convert the coupled \( I(t) \) curve into a curve for the particle size distribution, we obtain the result shown in Figure 12. The bold line is the integral form and the fine line the differential form of the coupling particle size distribution. The differential form demonstrates the excellent resolution of our particle size distribution equipment especially well. All ten components of this extremely broadly distributed dispersion are separated down to the baseline, including the two components at 318 and 356 nm respectively, even though their diameters are only approximately 12% apart. The “given” values in the left table of Figure 12 were used to prepare the
dispersion, and the “reproduced” values in the right table were obtained empirically by measuring the mixture of ten components. We were able to reproduce the diameters to within 5% and the proportions of the mixture to within 15%. This shows that our coupling particle size distribution technique works for dispersions with an extremely broad distribution. We also tried to measure the particle size distribution of this ten-component latex mixture by sedimentation FFF,\(^{15}\) but this method was not able to reproduce the correct mixing ratio. This demonstrates the superiority of the AUC method (see also Lange\(^{11}\)).

### 7 EXAMPLES OF ANALYTICAL ULTRACENTRIFUGATION PARTICLE SIZE DISTRIBUTION TECHNIQUE

It should be emphasized that we can measure the size distribution of particles contained in pigment preparations, paints and emulsions as well as those contained in polymer dispersions, that is to say any kind of dispersed microparticles having diameters in the range from 10 to 3000 nm. Nonspherical particles such as ellipsoids, cubes, rods or needles can be also measured, but the measured “diameter” is that of a Stokes-equivalent sphere. The dispersant does not necessarily have to be water. Dispersed particles can be measured in any liquid medium, including organic solvents. This can be demonstrated by a few examples.

Figure 13 shows needle-shaped crystals of a copper phthalocyanine pigment. A micrograph of the needle-shaped crystals in Figure 13 with an optical image processing computer program to measure the electron microscope (ELMI) particle size distribution of the needle length, which is also shown in Figure 13. The ELMI particle size distribution is not very accurate, because we counted only 991 particles and it was very difficult to distinguish between neighboring particles. Nevertheless the AUC particle size distribution agreed reasonably well with the ELMI particle size distribution. The ELMI particle size would be expected to be higher, because the needle length (ELMI) is being compared with the equivalent sphere diameter (AUC).

Figure 14 shows another example with nonspherical particles. Instead of being dispersed in water, the heavy (\(\rho = 4.2 \text{ g cm}^{-3}\)) Mn/Zn ferrite nanoparticles were dispersed in the organic solvent triethylene glycol (TEG).
The dispersion is a magnetic fluid which is switchable in a magnetic field, and it may perhaps be used in the near future in coupling devices, seals and dampers. Our task was to study the agglomeration of the primary 20-nm particles under different conditions. In the special case shown in Figure 14, it was found that the dispersion consisted of 20% w/w of primary 20-nm particles and 80% w/w of highly agglomerated particles with diameters between 40 and 400 nm.

Figure 15 shows an example of historical importance, the original sample of Rinde and Svedberg: \(^1\) pure colloidal gold particles with a very high density of \(\rho = 19.3 \text{ g cm}^{-3}\) (and a complex refractive index \(n(Au) = 0.706 + i \cdot 2.42\) at \(\lambda = 546\) nm and \(T = 25\) °C, which we use for the Mie theory). These gold particles have an extremely small diameter \((D = \text{5 to 50 nm})\), which demonstrates the lower measuring limit for particle diameters of the AUC particle size distribution method with a light scattering/turbidity detector. The gold nanoparticles themselves are embedded in a transparent film of polyvinylpyrrolidone, as the electron micrograph in Figure 15 shows. For the AUC particle size distribution measurement we simply dissolved this film in water. There is a reasonable agreement between the ELMI and AUC results. The film itself has been tested as a fast nonlinear optics switch for optical computers.

Figure 16, our last example, demonstrates that the AUC particle size distribution method works very well with emulsions, including liquid nanodroplets.

We prepared an aqueous 10% w/w emulsion of two monomers by mixing 50% w/w styrene and 50% w/w stearyl acrylate, stirring them with an Ultra Turrax® mixer and applying ultrasound. We describe this emulsion as a mini-emulsion, because the diameters of the monomer droplets are about 100–500 nm, as the AUC particle size distribution in Figure 16 shows. This mini-emulsion remains stable for 2 weeks, because the hydrophobic stearyl acrylate acts as a cosurfactant. We measured the density of these liquid droplets by H2O/D2O analysis, and obtained a result of \(\rho = 0.882 \text{ g cm}^{-3}\). We polymerized the droplets by increasing the temperature and adding a water-soluble initiator. We then again measured the particle density of the resulting polymer dispersion by H2O/D2O analysis, and obtained a result of \(\rho = 0.984 \text{ g cm}^{-3}\). The AUC particle size distribution is also shown in Figure 16. As expected, the droplet/particle density increased due to polymerization, but the particle size distributions of the monomer droplet emulsion and the polymer latex particles are identical.

8 OUTLOOK – THE NEW TWO-LASER-BEAM TECHNIQUE AND VERY SMALL (1–20 nm) PARTICLES

This section deals with two current topics. Firstly, how is it possible to increase the precision and resolution of the AUC particle size distribution method with the light scattering/turbidity detector for particles with a diameter of \(10–5000\) nm? Secondly, how can we measure extremely small particles \((1–20\) nm) which scatter hardly any light and cause hardly any turbidity?

The experimental set-up with one (laser) light beam, described in Figure 2, may offer a solution to the first problem, but it has three disadvantages:

1. It is not always possible to fill the measuring cell up to exactly the same height, because small air bubbles with different sizes are formed during the
filling process. This results in an error $\Delta r_M$ in the radius of meniscus $r_M$ (see Figure 4) and, according to Stokes’ law, the particle diameter $D$ as well. Thus if we could reduce $\Delta r_M$ we could reduce the error in $D$ too.

2. Because we never know if the particles of an unknown dispersion will form a sediment or float to the surface, we position the laser beam in the middle of the cell between the radius of the meniscus $r_M$ and radius of the base $r_B$. Thus we always use only the half of the maximum possible running distance ($r_B - r_M$) of the particles. Increasing the running distance would also increase the range of diameters which can be measured.

3. In $\text{H}_2\text{O}/\text{D}_2\text{O}$ analysis, we always need a third cell with the dispersion medium 50% $\text{H}_2\text{O}$: 50% $\text{D}_2\text{O}$ to allow the computer to recognize whether the unknown dispersion particles form a sediment or float to the surface, i.e. whether we have to use $r_M$ or $r_B$ in our calculations, according to Stokes’ law in Figure 4. If we did not need to use this third cell, we could run three $\text{H}_2\text{O}/\text{D}_2\text{O}$ analyses simultaneously in an eight-cell rotor instead of only two.

To circumvent these three disadvantages of the set-up shown in Figure 2, we have devised a new set-up, shown in Figure 17 by introducing a second parallel measuring beam.

We can change the radial position of the two laser beams, the inner and outer positions $r_1$ and $r_2$, continuously between $r_M$ and $r_B$. It is still not clear what their optimum position is. The preliminary measurements presented in Figure 18 were made at two different positions, at one-third and two-thirds of the way along the distance $r_B - r_M$.

The right side of Figure 17 shows a measurement performed on a monodisperse latex. The two simultaneously measured $I(t)$ fractionation curves are steep one-step curves. Both of them and – very importantly as a third possibility – the difference between them deliver the particle size distribution of the measured latex according to Stokes and Mie, if the particle density and the refractive index are homogeneous and known. The computer calculates which of the three particle size distributions is the best one. If the particles form a sediment (and if $r_M$ is precisely known) the outer particle size distribution is best. If the particles float to the surface ($\rho_P < \rho_{DM}$) the inner particle size distribution is best. If $r_M$ is not precisely known (because of air bubbles of different size or a small leakage in the cell) the difference between the inner and outer curves gives the best particle size distribution because we do not need to know the value for $r_M$ to be able to calculate it. Instead, we need to know the value for the new “running distance” ($r_2 - r_1$), which has to be measured once only and is then constant for all cells and every new run. Figure 18 shows an example of a measurement made with this new two-laser-beam set-up.

The insert in Figure 18 shows the two simultaneously measured $I(t)$ curves (and the exponentially increasing rotor-speed curve $N(t)$) for a 1:1:1 mixture of three monodisperse polystyrene calibration latices with known diameters of 120, 550 and 1300 nm. These two $I(t)$ curves and the difference between them, $I(t)_{\text{inner}} - I(t)_{\text{outer}},$

![Figure 17](image_url)

**Figure 17** Schematic diagram of a two-laser-beam set-up in an ultracentrifuge used to measure particle size distribution. (Reproduced from Mächtle(11) by permission of Biophysical Society.)
can be transformed according to Stokes and Mie into the three particle size distribution curves shown in Figure 18 (the differential particle size distribution is shown alongside the integral particle size distribution). There is fairly good agreement between these three particle size distribution curves. The mixing ratio and the diameters are reproduced to within \( \pm 5\% \).

There are some small differences between the three particle size distribution curves, but we will not discuss them here because these are the very first measurements that we have made with our new two-laser-beam set-up. These issues will be discussed in a forthcoming paper. However, there is evidence to suggest that the difference between the curves gives the most precise particle size distribution and also the highest resolution. The main lesson to be learnt here is that Figure 18 demonstrates that our new concept actually does work.

It can always be seen from the two \( I(t) \) curves (as shown in the insert of Figure 18) whether sedimentation or flotation takes place within the latex. If the running time of the particles in the outer beam \( t_{\text{outer}} \) is higher than in the inner beam \( t_{\text{inner}} \), the latex forms a sediment. If \( t_{\text{inner}} > t_{\text{outer}} \) is valid, the latex particles float to the cell meniscus. This behavior can be distinguished very easily by a computer. This is important for the H\(_2\)O/D\(_2\)O sedimentation analysis, because it can then be performed without the 50 : 50 H\(_2\)O/D\(_2\)O mixture.

The answer to the second problem is simple: we have to use other detectors for nonturbid, very small (1−20 nm) particles instead of light scattering/turbidity detectors. We need to use refractive index detectors (schlieren or interference optics) or UV-absorption detectors, as in the case of dissolved molecules with high and low molar masses. Mächtle\(^{13}\) presents an example of a measurement made of 5−25 nm SiO\(_2\) particles, performed with the famous old Model E AUC device from Beckman fitted with schlieren optics. The best example\(^{12}\) in the literature of this aspect of inorganic colloids, performed with the latest AUC instrument (the OPTIMA-XL-IA from Beckman, which has a 180−900 nm UV scanner and interference optics), is presented in Figure 19. It shows the AUC particle size distribution of extremely small (0.4−2.0 nm) particles of colloidal platinum (aqueous sol, \( \rho_{\text{Pt}} = 24.45 \text{ g cm}^{-3} \)) in angstrom resolution performed with the UV scanner at \( \lambda = 380 \text{ nm} \), at 25°C and maximum constant rotor speed of 60 000 rpm. The resolution is nearly atomic. Figure 19(a) shows different radial UV scans at intervals of 2 min. The bold line is transformed by Stokes’ law into the particle size distribution in Figure 19(b). Different scans yield nearly the same particle size distribution (if they are not too early or too late), indicating that diffusion effects do not have a disruptive effect. We believe that inorganic colloidal (1−20 nm) particles of this type will play an important role in the near future in metal sols, semiconductors and nonlinear optics. AUC makes it possible to study their growth mechanisms.\(^{12}\)

**Figure 18** Three AUC particle size distribution curves of a mixture of three monodisperse polystyrene calibration latices (120:550:1300 nm (1:1:1 wt. parts), calculated from the two \( I(t) \) curves shown in the insert and from the difference between the curves for \( I(t)_{\text{inner}} - I(t)_{\text{outer}} \). Diffraction in Particle Size Analysis

Bruno Novales
Institut National de la Recherche Agronomique, Nantes, France

1 Introduction

The diffraction techniques for particle size analysis are based on the measurement of the angular distribution of light diffracted by particles situated in the path of a light beam. These techniques have been used for many years to measure the size of small particulates but the calculation to generate a particle size distribution is so complex that it is only in the last 15 years with the development of small, inexpensive, and powerful computers that these techniques have become so popular. The complete theory describing the diffraction of light by a spherical particle was described by Mie in 1908 and is able to predict the electromagnetic field at any point in space. This theory is adequate for particles with diameters of the same order as the wavelength of the incident light. Some other models have been presented. The most commonly used are based on the Fraunhofer diffraction theory. Light-scattering techniques have obvious advantages for particle size analysis as compared to other methods. They are faster than mechanical techniques, nonintrusive, nondestructive and do not require large amounts of sample. These techniques can be performed on dry powders or on suspended particles in a liquid or in a gas. The operating range of light diffraction techniques is from 20 µm to several millimeters. This article presents the main theoretical aspects of light diffraction by particles. Also, a brief description of a diffraction particle sizer is given with some practical recommendations. Problems related to particle size analysis by light diffraction are examined. Some other light-scattering methods (photon correlation spectroscopy, single particle scattering, Doppler techniques) are also presented.

1 INTRODUCTION

Particle size is an important physical parameter in many complex systems. In many industries, raw materials are processed to be converted into finished products. The processes include grinding, sieving, mixing, and heating operations. Each of these operations is affected by the particle size. So, it is not surprising that many techniques have been developed for particle size analysis. Current methods include techniques based upon sieve analysis, microscopic and image analysis, electrical and optical sensing zones, sedimentation, elutriation, and chromatography.

In recent years, techniques involving light-scattering for particle size analysis have become increasingly popular due to laser light sources and the development of condensed but powerful microcomputers which are inexpensive. Techniques involving light–particle interactions have certain advantages for particle size analysis compared to other methods. Also, they are easy to manipulate as many scattering instruments are considered as black boxes from a user point of view.

In fact, light-scattering techniques cover several methods, amongst which light diffraction techniques are the most commonly used. The latter are based on the measurement of the angular distribution of light diffracted by particles in a light beam path. The intensity scattered in any particular direction depends on the size of the particles and their optical properties. If the scattered light
is measured as a function of the angle, the resulting scattering pattern contains information regarding the particle size, which can be assessed by appropriate calculations. The extraction of this information is rather mathematically complex and will ultimately result in a particle size distribution. Particle size analysis using diffraction techniques can be performed on dry or suspended particles in a carrier. They are particularly well adapted for particles ranging from 20 to 3500 μm.

Other techniques based on light properties also provide particle size evaluations. Amongst these, we consider single particle scattering, photon correlation spectroscopy, or Doppler techniques. The first refers to the measurement of the intensity of the scattered light from each particle individually at a fixed angle. The amplitude of the scattered light pulse is used to compute the particle size. These instruments are also called single particle optical counters (SPOCs). Photon correlation spectroscopy is designed for assessing the size of particles from 10 to 500 nm. In effect, these instruments measure the fluctuations of scattered light generated by the particles due to their Brownian motion. Since large particles diffuse more slowly than small, fluctuations in scattered light are indicative of the particle size, assuming that some essential restrictions are fulfilled.

The application of these techniques grows steadily making them increasingly popular versus traditional techniques. A few years ago, light-scattering instruments were mostly found in research laboratories, whilst now some are already inserted for on-line production control. In that sense they cover fields such as food production, pharmaceuticals, and coatings.

# 2 THEORY OF LIGHT DIFFRACTION

When a light beam interacts with a particle, it can be absorbed, transmitted, or scattered. Scattering of light concerns the dispersion of the light beam at any angle by the particle. The theory of light-scattering by a particle has been developed by many authors, especially Mie, Rayleigh, and Fraunhofer, and has been reviewed in many books and articles.

## 2.1 Mie Theory

The general theory describing the scattering of light by a spherical particle has been formulated by Mie. It allows the energy of the scattered light to be calculated as a function of the particle size, its refractive index, the wavelength of the incident beam, and the angle of observation. It is derived by solving Maxwell’s equations for the incidence of a plane wavefront on a particle and is mathematically complex and does not result in simple analytical solutions. Therefore it is often necessary to make many restrictions and simplifications to become usable. Even in these conditions, proper angular distribution of scattered light is only accessible for quite simple particle shapes, such as spheres which will behave ideally. Consequently, almost all light-scattering techniques assume the particles to be spherical and provide subsequently corresponding equivalent diameters. In order to be able to obtain the scattering pattern of a particle, it is necessary to specify the refractive index of the particle, the refractive index of the suspending medium, the particle size, and the wavelength of the light beam. If for some standard materials the refractive index is an established parameter, problems may arise when biological or food products are considered. Moreover, for very small particles, the angular intensity distribution is dependent on the polarization of the incident light. As a concluding remark, it can be stated that Mie theory is applicable for particles whose size is of a comparable order to the wavelength of the incident light.

For particles shorter than the wavelength of the incident beam, Rayleigh scattering theory is available. For particles larger than the wavelength of the incident beam, Fraunhofer theory can be applied.

## 2.2 Rayleigh Scattering

If the particles are very small compared to the wavelength of the incident light, they can be considered as opaque points wherein light is not able to penetrate. According to the Rayleigh theory, the scattering pattern is independent of the shape of the particle, as they are considered as points. This leads to a very simple scattering pattern identical to that obtained from the Mie theory for particles of very small size. According to this theory, the scattering intensity $I$ at an angle $\theta$ is given by Equation (1):

$$ I = I_0 a^2 \left( \frac{2\pi}{\lambda} \right)^4 \frac{1 + \cos^2 \theta}{2r^2} $$

where $I_0$ is the incident intensity, $r$ is the distance from the particle to the detector, $\lambda$ is the wavelength of light, and $a$ the particle polarizability which for spheres is given by Equation (2):

$$ a = \frac{3(m^2 - 1)}{m^2 + \frac{2}{4}} V $$

with $m$ the relative refractive index and $V$ the volume of the particle. The scattering intensity is thus proportional to the sixth power of the particle diameter. It follows that small changes in size will greatly affect scattered intensities. However, small particles scatter a very small amount of light. It is also understood that the study of the scattering properties of these small particles is very limited.
2.3 Fraunhofer Scattering

Fraunhofer scattering is a diffraction theory which was developed for large opaque particles. It assumes that light that has penetrated into the particles does not contribute to the diffraction pattern, so the particles are considered as completely opaque. Consequently, this theory does not take into account the optical properties of the particles. It is very useful for the calculation of the size distribution of particles of several micrometers and even higher. Most of the earlier laser diffraction instruments are based on this theory.

The Fraunhofer diffraction theory is sometimes described as the light-scattering caused by the edges of an aperture. Babinet's theorem explains that the diffraction pattern obtained with an aperture of given size and shape is the same with an opaque object (particle) of equivalent size and shape. Two requirements are needed to obtain a diffraction according to the Fraunhofer theory: the size of the aperture (or the particle) must be small in relation to the distance between its position and the light source and the diffraction must be observed at infinite distance. In that case, the diffraction patterns of particles having the same size superimpose perfectly. The first requirement can be satisfied by considering a plane wave incident on the diffraction plane. The second requirement can be satisfied by placing the detector far away from the aperture or by using a lens in order to focus the diffracted light onto a detector at the focal plane of the lens.

For a given spherical particle, the Fraunhofer theory allows the intensity of the scattered light to be defined as shown in Equation (3):

$$I = I_0 \frac{2J_1(x \sin \theta)}{x \sin \theta}^2$$  \hspace{1cm} (3)

where $I_0$ is the intensity of the incident light, $\theta$ is the diffraction angle, $J_1$ is a Bessel's function of first order, and $x$ is a parameter, often called the size parameter, given by Equation (4):

$$x = \frac{2\pi r}{\lambda}$$  \hspace{1cm} (4)

where $r$ is the particle radius and $\lambda$ the wavelength of the incident light.

The scattering is observed for small angles and in this case it is possible to write Equation (5):

$$I = I_0 \frac{2J_1(x \theta)}{x \theta}^2$$  \hspace{1cm} (5)

The angles for which the diffracted intensity will cancel depend on the particle size and the ring of order $k$ corresponding to beams diffracted at the angle given by Equation (6):

$$\theta_k = \frac{\lambda}{2\pi r} m_k$$  \hspace{1cm} (6)

where $m_k$ is the value for which the function $J_1$ is equal to 0. The radius of a diffraction ring is conversely proportional to the particle diameter. It follows that small particles will scatter light at larger angles, whereas large particles scatter at smaller angles (Figure 1).

The diffraction pattern of the light onto the detector will exhibit intensity variations as a sequence of minima and maxima (Figure 2a) which correspond to a series of concentric rings alternately dark and bright, with a more intense disk at the center (Figure 2b).
The particles are not analyzed individually. The intensity at the detector is the result of the light diffracted by the particles in the analyzed sample whatever their size as defined by Equation (7):

\[ I = C \int_0^\infty N(r) r^4 \frac{J_1(x\theta)}{x\theta}^2 \, dr \]  

where \( N(r) \) represents the population of particles of size \( r \) and \( C \) is a constant. The size classes and the angles for which the diffraction is measured are fixed. The diffraction model is an additive model for which the constants are fixed by the instrument and the unknown parameters are the ratios of the distribution. Mathematical algorithms are required to transfer light intensities into particle sizes. For polydisperse systems the diffraction pattern of each particle size overlaps with those of the same order in the system. As a consequence, the mathematical algorithms and necessary assumptions required for the calculations are very complex. For the instruments available, these algorithms are strictly confidential and in general fit between observed and theoretical intensities which will be obtained by a population of spherical particles.

3 DESCRIPTION OF A LASER DIFFRACTION PARTICLE SIZER

In Figure 3, the principle of a diffraction particle sizer is illustrated. The light source is a helium–neon laser generating light at a wavelength of 633 nm. It provides a better stability and a higher signal-to-noise ratio than lasers with higher wavelength. The beam diameter is about 1 mm, so a beam expander is mounted in order to produce a uniform parallel beam of nearly 10 mm in diameter in order to monitor a useful sample volume. The expanded beam passes through the sample cell and the diffracted and transmitted light is focused by a lens onto the detector in the focal plane of the lens. The latter is often a Fourier lens providing a Fourier transform image of the scattered light. Every parallel light beam emitted from the sample at a given angle \( \theta \) will be focused in the focal plane at the same azimuth and at a position \( X = F(\theta) \) (Figure 4). This very interesting property means that the diffraction will be independent of the position of the particles in the light beam. The undiffracted light is focused at the center of the detector and evacuated through a pinhole. The detector generally consists of photosensitive silicon rings with increasing widths. Since the light scattering at large angles may be several orders of magnitude less than that near the center, the external rings should have a subsequent higher sensitivity or surface. The signal at a specific position on the detector corresponds to the light intensity scattered at a definite angle, whatever the position of the particle in the sample cell. The smaller particles detected are estimated at 1 \( \mu \)m. The focal length sets the size of the diffraction field and then the range of measurements. A large focal length enables the resolution at the center of the diffraction rings to be improved, allowing larger particles to be analyzed.

4 PRACTICAL MEASUREMENTS

4.1 Particle Size Range

The lower diffraction limit will correspond to the limit of validity of the geometrical laws of optics. It will be influenced by the relative refractive index of the particles. For water, this value is set at 1.33. When the relative refractive index is closer to 1, this limit can increase. The upper limit of size analysis by diffraction is due to the lack of resolution near the central bright point on the detector.

4.2 Sample Preparation

The samples should have homogeneous physical properties (refractive index, volumetric mass, etc.). For measurements in the liquid phase, the choice of the suspending medium is very important. The dispersion
can be facilitated by ultrasound or with appropriate additives. However, the dispersion method should not modify the sample. The refractive index of the powder must differ from that of the suspending medium. It must be transparent to the incident laser beam and the refractive index must be stable during the experiment. The main cause of variations of the refractive index is temperature changes. These variations lead to a contribution of the small angles corresponding to an overestimation of the larger particle sizes. If large particles are to be measured in a suspending medium, the flow rate should be set to the minimum value that will allow them to be suspended without sedimentation. Sufficient time should be allowed for a perfect mixing of the suspension before a measurement. The most commonly used suspending media are water, methanol, ethylene glycol, and trichloroethylene.

Dry powders can be analyzed by sending the sample through the laser beam when free-flowing. The dry powders are blown through the light beam by compressed air and evacuated by a vacuum cleaner. If the particles are cohesive, the material may not be properly dispersed. The advantage of dry measurements is that the quantity of sample analyzed is not limited. It is then possible to perform a measurement from 100 mg to several kilograms with a continuous flow rate. This may avoid the preparation of a representative sample, which is often a critical step.

Laser diffraction is also particularly well adapted for aerosol sizing since many liquid droplets measure several micrometers. It is necessary to spray the aerosol into the laser beam during the measurement.

4.3 Sample Amount

The sample amount does not play a part in the measurement, except for the representativeness. However, for measurements in a liquid phase, an optimal concentration of the sample in the suspending medium is needed to avoid multiple scattering problems (see below). Most of the commercially available instruments set the concentration in the sample cell by measuring the light absorbed by the sample. The optimal concentration is obtained for an absorbance of 0.1–0.25. If the concentration is too low, too few particles are measured and the statistical errors predominate. Generally, the quantities required for an optimal measurement are about 1–2 g for liquid measurements, and 20–40 g for dry measurements.

4.4 Experimental Measurements

The focal lens is chosen according to the range of particle size studied. An analysis consists first of taking data for the background and then for the sample. The background is subtracted from the sample signal. Both measurements need to be done in the same operational conditions. This is easily done for a measurement of a suspension in a liquid. The background is acquired by injecting the suspending medium alone. Then the particles are added to the sample cell. A protocol is established for each kind of powder which determines the stirrer speed, the pump speed, the air pressure, the use of ultrasound, etc.

4.5 Results

We have seen above that it is possible to calculate the scattering pattern from a sample of known size distribution by using a particular theory (Mie, Rayleigh, Fraunhofer). It is also necessary to solve the inverse problem in order to obtain a particle size distribution from a scattering pattern. From a practical point of view, it is almost impossible to find the particle size distribution from the scattering pattern by applying only simple algebraic operations.

In fact, a first distribution is roughly calculated from the scattering pattern by examining any maximum of intensity in that pattern. Then the scattering model that would be obtained from that distribution is calculated by using the appropriate model. The difference observed between the calculated and the experimental pattern are used to correct the distribution. This procedure is applied until the difference between the two patterns is a minimum.

The transformation of light intensities into a size distribution can be done by assuming an a priori distribution shape (normal or log normal distribution for instance) or by fitting each class of particle size in the

Figure 5

Particle size distribution obtained with a laser light diffraction apparatus. Sixty-four size classes are calculated. The line corresponds to the cumulative percentages. The histogram represents the percentage of particles in each size class.
distribution independently of each other. In many cases, the distribution shape is not known. This is particularly true when the particles are heterogeneous in size and the distributions are multimodal. The size distribution obtained by laser diffraction is expressed in percentage of mass or in volume (by assuming that the density of a particle is independent of its size).

Figure 5 shows an example of particle size distribution obtained with a laser light diffraction instrument. The results can be expressed either as the cumulative percentages of particles or by the percentage in each particle size class.

5 PROBLEMS RELATED TO SIZE ANALYSIS BY LIGHT DIFFRACTION

Even though diffraction techniques have numerous advantages over other techniques, they also suffer from a large number of potential sources of systematic errors, particularly when calculating the particle size distribution. The factors which may cause inaccuracies of particle size distribution obtained by diffraction techniques are the following:

- the Fraunhofer diffraction cannot be applied to small or transparent particles. The Mie theory requires some optical properties of the particles to be known (for example the refractive index) which may not be easily accessible for the user;
- influence of the particle shape on the diffraction pattern, which may lead to an overestimation of the larger particles caused by large-angle diffraction due to the presence of edges on the particles;
- overlapping of the size classes in polydisperse systems leading to misinterpretation of the diffraction pattern;
- unknown computer algorithms for transforming the diffraction pattern into a distribution, which could vary from one manufacturer to another.

5.1 Submicrometer Measurements

As the Fraunhofer theory does not apply to systems composed of particles whose sizes are not significantly larger than the wavelength of the incident light, the examination of submicrometer particles by Fraunhofer methods is questionable. Some authors have shown sizing error greater than 20% in the mean diameter for particles in the 2–7 µm range. This is due to the fact that the scattering of the smallest particles is extremely weak. This is not such a problem if only small particles are present in the system. However, when small particles are mixed with larger ones, whose scattering is many times stronger, the smallest particles may not be detected on the scattering pattern. The use of the Mie theory to solve the problem of submicrometer particles, while a possible improvement, is not always satisfactory as the optical parameters required for the necessary calculations may be unavailable. Particularly, it is often impossible to know the refractive index of the particles in complex systems. To measure the size of very small particles, photon correlation spectroscopy can be used if the particles are in suspension and do not sediment.

5.2 Particle Shape

As indicated previously, the diffraction pattern can only be analyzed for simple shapes. For complex or irregular particles, it should be interpreted with caution. Nathier-Dufour et al. have shown that particles having complex shapes (nonspherical) exhibit diffraction patterns containing large-angle scattered beams. If Fraunhofer theory is used to calculate the particle size distribution then the proportion of small particles may be overestimated. If particles of a given size are very irregular, the size distribution may exhibit artefact peaks indicating that more than one particle size is present in the sample. A shape factor may be proposed for nonspherical particles to correct for the effect of the shape on the scattering pattern but this implies that all the particles in a given sample have the same shape.

5.3 Multiple Scattering

The light-scattering models assume that each photon encounters only one particle. When a photon is scattered by a series of particles, its incidence angle will be known only for the first encounter and then the scattering pattern could not be interpreted. This phenomenon is called multiple scattering and is highly undesirable in many cases. It results in larger diffraction angles, since light scattered once is no longer parallel when it encounters another particle. This leads to an overestimation of the small particles. To ensure that no multiple scattering occurs, it is important to keep the sample perfectly dilute.

5.4 Calibration

Laser diffraction instruments do not need calibration in the usual sense. The diffraction pattern can be converted into a size distribution without standard measurements since they are based only on fundamental physical properties. It is however important to regularly check the instrument performance in order to ensure that it gives a relevant particle size distribution. This can be done by measurements of the monodisperse standards distribution covering the range of the instrument. The most generally available standards are latex particles.
5.5 Data Processing Artefacts

Generally, the fitting models are accurate for monodisperse samples in the center of the measuring range. For polydisperse systems, particles having close sizes will lead to an overlapping of their diffraction pattern. For commercially available instruments, the algorithms used for the transformation of the diffraction pattern into a distribution are unknown to the user. The manufacturer’s assumptions and their effect on the resultant particle distribution are not generally verifiable. Moreover, the calculations are so complex that approximate theories or iterative methods are used and each manufacturer provides its own algorithm which may lead to differences in the results from different instruments using the same sample. It is then always necessary to compare particle size distribution obtained by laser diffraction with other independent methods.

5.6 Intercomparison of Laser Diffraction Instruments

Some work has been done to compare results of various laser diffraction instruments. For instance, Etzler and Sanderson\(^{(19)}\) have shown that different Fraunhofer instruments could produce largely different particle size distributions from the same material. This indicates that the results obtained from any given instrument may not accurately describe the powder and thus may lead to incorrect technical recommendations. These authors suggest the results obtained with one laser instrument should be compared with those of an other independent method to insure against the presence of instrumental artefacts.

6 OTHER LIGHT-SCATTERING METHODS FOR PARTICLE SIZE ANALYSIS

6.1 Single Particle Scattering

The principle of single particle scattering instruments is very simple. The particles are passed in an air jet through a light beam and scatter a light pulse whose duration is proportional to the time taken to pass through the beam and whose intensity depends on particle size. These instruments are called SPOCs. They are well adapted for particles with sizes up to about the wavelength of light. They offer the advantage of providing an absolute concentration in terms of the number of particles per unit volume. However, since each particle is analyzed separately these instruments are slower than Fraunhofer instruments which average the particle sizes over the particles present in the sample.

6.2 Photon Correlation Spectroscopy

Photon correlation spectroscopy, also known as quasi-elastic or dynamic light-scattering\(^{(20)}\) is a method of size measurement for suspensions of spherical particles in the 20–500 nm size range. In a typical photon correlation spectrometer, particles are illuminated by a laser beam. The scattered light is detected at an angle \(\theta\) with respect to the incident direction. Since the particles are continuously displacing due to Brownian motion, the observed scattered intensity will fluctuate along the time axis. Therefore, the analysis of these fluctuations as a function of time provides information on the mobility of the particles. This mobility is related to the diffusion coefficient and the latter to the particle radius. Since large particles diffuse more slowly than small ones, the fluctuations in scattered light intensity from large particles occur over a longer timescale than fluctuations induced by small particles. The problem for photon correlation spectroscopy is to extract the quantitative information from the fluctuations. This can be done by an autocorrelation analysis. The autocorrelation function \(G(\tau)\) of a fluctuating intensity is defined in Equation (8) as the product of the intensity at an instant \(t\) and the intensity at an instant \(t + \tau:\)

\[
G(\tau) = \langle I(t)I(t + \tau) \rangle \tag{8}
\]

This correlation function depends only on the time difference \(\tau\) and is independent of the arbitrary time \(t\). The symbol \(\langle \cdots \rangle\) indicates that \(G\) is an average of \(I(t)I(t + \tau)\) for various times \(t\).

For monodisperse small spherical particles, this autocorrelation function is essentially an exponentially decaying function of the time difference \(\tau\) and can be written as shown in Equation (9):

\[
G(\tau) = A + B \exp(-2Dq^2\tau) \tag{9}
\]

where \(A\) and \(B\) can be considered as instrumental factors and \(D\) is the diffusion coefficient, with \(q\) being given by Equation (10):

\[
q = \frac{4\pi n}{\lambda} \sin \left(\frac{\theta}{2}\right) \tag{10}
\]

with \(n\) the refractive index of the medium, \(\lambda\) the laser wavelength, and \(\theta\) the scattering angle. The particle size is obtained by relating it to the diffusion coefficient. However, there is no general relation that applies in all situations. With the assumption that the particles are spherical and noninteracting, the particle diameter \(d\) is obtained from the Stokes–Einstein equation shown in Equation (11):

\[
d = \frac{kT}{3\pi nD} \tag{11}
\]
where \( k \) is the Boltzmann constant, \( T \) the absolute temperature, and \( \eta \) the shear viscosity of the solvent.

For a polydisperse system, the size distribution is obtained by deconvolution of the sum of all the single exponentials contributing to the measurement of the autocorrelation function.

### 6.3 Laser Doppler Velocimetry

Laser Doppler velocimetry is a velocity measurement technique based on the Doppler shifting properties of moving particles, as they interact with light. In laser Doppler velocimeters, the laser beam is divided into two and the focusing lens forces the two beams to intersect, creating interferences (Figure 6). The interferences of the light beams in the measurement volume create a set of equally spaced fringes (light and dark bands) that are parallel to the bisector of the beams. A measurement is made when a particle being carried by the flow passes through these fringes. The light scattered by the particle will have a frequency (the Doppler frequency) proportional to the fringe spaces and to the component of its velocity normal to the fringes.

Two main techniques can be used to relate the Doppler frequency to the particle size. The first method is based on the interpretation of the Doppler signal shape generated by a particle moving through the fringes, which depends of the ratio of the particle size upon the interfringe space. However, this method leads to good results only if the Doppler signal is of good quality. As a consequence, this method is often replaced by the phase Doppler technique.

In phase Doppler velocimeters, multiple detectors are used to collect the light scattered by a single particle. The principle is that if two light sources of the same frequency, but at different angles, are scattered from a single moving particle, the light reaching the detectors will have the same frequency but phase Doppler shifts. This is a result of the fact that when a particle passes through the beams, it does not uniformly illuminate the receiving lens. The diffraction pattern passes over it from one side to the other. As a consequence, the signal will be received in the detectors at slightly different times, i.e. the separate detector signals are out of phase. These phase differences can be related to the particle size if the relative refractive index of the particle is known. For particular positions of the detectors, the relation between the phase shift and the particle size can be considered as linear.\(^{(21)}\) The phase Doppler method requires no calibration because the particle size and velocity are dependent only on the laser wavelength and on the optical configuration. Phase Doppler measurements are not based upon the scattered light intensity, and consequently, are not subject to errors from beam attenuation or deflection.

### 7 CONCLUSION

This article has attempted to show the main advantages of particle analysis by light diffraction in terms of usefulness, rapidity, and performance. This technique can be used for particles ranging from 1 \( \mu m \) to more than 3000 \( \mu m \). It can be adapted for dry or suspended particles in a liquid phase, for aerosols and emulsion. It is a nonintrusive and nondestructive technique, very easy to use even if the mathematical theories to obtain a particle size from the diffraction pattern are very complex. The results are obtained very rapidly (less than 1 min to obtain a particle size distribution) with good repeatability. With all these advantages, it is not surprising that light diffraction techniques are being increasingly used for particle size analysis and will replace “traditional” techniques in many fields in the coming years.

Electrozone Sensing in Particle Size Analysis

M. Margarida Figueiredo
Coimbra University, Portugal

1 INTRODUCTION

Almost every solid material either starts out as a powder, ends up as a powder, or goes through at least one powder stage during manufacture. It is thus not surprising that powder technology plays such an important role throughout process industries, including areas as diverse as chemicals, foods, agricultural products, mineral processing, ceramics, cements, advanced materials, defense, and the environment. In the chemical industry, for example, 60% of the products are manufactured in particle form and a further 20% use powders to impart specific properties to the final products. Moreover, it has been widely recognized that the behavior and properties of the end products are highly dependent upon the characteristics of the particles from which they are formed, namely particle morphology (shape and texture), size, and size distribution.

In principle, any aspect of particle behavior which is dependent on particle size can be used to measure that size. This explains, at least partly, the great variety of instruments commercially available which, despite their differences in configuration and degrees of sophistication and automation, are based on only a few physical principles.

Electrozone sensing (also named the electrical sensing zone method) is the most widely used of the so-called stream scanning methods where particles are measured one at a time. In these methods, particle size is determined by the interaction between the particles and an external field which can be an electrical field (electrozone sensing) or a light beam (optical sensing). Electrozone sensing was originally developed by Wallace Coulter (and so is frequently known as the ‘Coulter principle’) in the late 1940s for counting blood cells rapidly, but was only patented in 1953 and described in detail much later. It has become very popular not only for counting and recent improvements of this technique. Finally, a list of commercially available equipment is supplied, together with its most relevant features.
sizing blood and other cells and organisms, but also for measuring the particle-size distribution of a wide range of particulate materials as drugs, pigments, fillers, toners, foodstuffs, cosmetics, explosives, construction materials, minerals, coatings, metals, and polymeric powders.

Electrozone sensing is the only method that measures a particle volumetrically, i.e. in three dimensions, and thus is less sensitive to particle shape, in contrast to optical sensing – indeed it is reasonably independent of this parameter, except for extreme shapes such as flaky particles. Additionally, the analyses can be carried out rapidly and with good reproducibility by semiskilled operators. As a result, this method has been the subject of a large number of studies and applications (biological and nonbiological), and is extensively described in textbooks. The technique has been accepted as a standard method by the British Standards Institution, as an AFNOR standard and, more recently, by the International Organization for Standardization (ISO), in addition to being recommended for many special applications.

As with other particle sizers, electrozone sensors have advanced significantly and the modern apparatus exhibits a range of specific features, including the storage, handling, and presentation of data. In particular, the main advantages of this technique are:

- it measures particle volume (one of the most representative expressions of particle size), for which it is often used as a reference method;
- the instrument response is not influenced by particle composition, density and refractive index or light interaction effects (inherent to many light blockage/scatter and diffraction systems);
- it produces accurate counts and high-resolution particle-size distributions;
- it is able to measure absolute concentrations (number or volume of particles per total volume of suspension).

The basic limitations are:

- the need to suspend the particles in an electrically conductive fluid;
- the necessity of prior calibration which, depending upon the degree of accuracy, can be laborious and, consequently, time-consuming;
- the limited size range (about 30:1 by diameter) covered by a single aperture, which requires the use of more than one aperture for very broad size distributions.

In summary, electrozone sensing presents a good combination of high resolution, size range, sensitivity, and mildness of secondary effects, and has been extensively used to measure particles from about 0.5 µm to approximately 1 mm, the upper limit depending mainly on particle density.

2 PARTICLE DETECTION PRINCIPLE

2.1 General Operation

In the electrozone measurement principle, particles homogeneously suspended at a low concentration in an electrolyte solution are forced to flow, substantially singly, through a small aperture (or orifice) in a nonconductive material that separates two electrodes of opposite potential (Figure 1). A current passing through the aperture between the electrodes enables the particles to be sensed by the changes in electrical impedance as they traverse the aperture.

The passage of a number of particles produces a train of pulses whose amplitudes are essentially proportional to the particle volumes. These pulses are then amplified, sorted, and counted. After instrument calibration, a distribution of the number of particles against volume, or equivalent volume diameter (usually denoted by $d_v$), can be obtained. This distribution is in turn easily converted

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{fig1.png}
\caption{Electrozone sensing operating principle. (Reproduced by permission of Beckman Coulter.)}
\end{figure}
to a volume-based distribution of $d_v$. As the volume of a particle is directly related to its mass through the density, the latter distribution is identical to a mass distribution for particles of uniform density.

The sample to be analyzed is dispersed in an electrolyte solution which is placed in a beaker and stirred. An orifice tube (a closed-end glass tube containing a precision-drilled hole) is immersed in the suspension and the flow through the orifice, controlled by a vacuum source, unbalances a mercury manometer (Figure 2).

Originally, all analyses were performed in the manometer (or siphon) mode. In this mode, the system is isolated from the vacuum unit but the flow continues as the mercury returns to equilibrium. The advancing column of mercury activates start and stop contacts, placed so that the count is carried out in a precise and reproducible volume of suspension (usually 0.05, 0.5 or 2.0 mL). This mode is therefore most useful for measuring particle concentration values (number or volume per total volume). Most modern instrumentation also operate in the manual mode, where data are acquired by manually initiating and stopping the counting, or in the time or count mode, in which the counting ends when the time period or the count reaches a preselected value.

As particles pass sequentially through the aperture, each displaces a volume of electrolyte equal to its own immersed volume producing a change in the resistance between the electrodes. As the current is maintained constant, these changes produce voltage pulses of short duration whose heights are essentially proportional to the volume of the particles. The pulses are amplified and fed to a threshold circuit having an adjustable threshold level. When this level is reached or exceeded by a pulse, the pulse is counted. (In some apparatus, the threshold level can be visualized on a small oscilloscope screen, facilitating the selection of appropriate counting levels.) The number of pulses counted represents the number of particles larger than some determinable value – the threshold value is related to the equivalent particle diameter through a calibration constant. In the simple models (called single-channel models), the usual procedure is to reset the instrument and initiate another count at a different threshold. Other instruments have upper and lower threshold circuits which permit sizing between two predetermined volumes (i.e. relative frequency distribution). Normally, in single and dual models, data are manually converted to the volume (or mass) distribution. More recent models are capable of multichannel analyses, i.e. the results can be simultaneously accumulated at a number of channels (size levels), typically between 16 and 256, in a very short time. The main advantages of multichannel analyses are the saving of operator time by removing repetitive counts and the ability to store the data in an internal or external computer for further processing. However, some authors claim that in some of these models a loss of counts may occur.\[10,14\] This is because it takes a finite time to process each pulse and, especially for relatively high count

![Diagram of the electrozone sensing analyzer.](image-url)
rates, it is possible that a significant proportion of counts may be lost. In general this will not affect particle-size distributions.

2.2 Sizing Response

Electrozone sensing measures particles by volume, assuming that the height of the pulses generated is directly proportional to the volume of the particles producing them. The reliability of the instrument therefore depends on the accuracy of this assumption. The relationship between the instrument response and particle size has been the subject of several theoretical models,\(^ {15-20}\) as there is no precise and simple solution with which to determine the change in resistance caused by the insertion of a nonconductive sphere in a conductive circular orifice.

This increase in resistance will be determined here using a simplified theory for ease of understanding.\(^ {16}\) Figure 3 shows a particle passing through the orifice and an element (slice) of the particle and orifice.

The resistance of the element without the particle is (Equation 1)

\[
\delta R_0 = \frac{\phi_f \delta l}{A}
\]

and the resistance of the element including the particle can be seen as two resistors in parallel (Equation 2):

\[
\delta R = \frac{1}{A - a \phi_f / l + A / \phi_s \delta l}
\]

where \(A\) is the cross-sectional area of the orifice, \(a\) is the cross-sectional area of the particle, \(\phi_f\) is the resistivity of the fluid, \(\phi_s\) is the resistivity of the particle, and \(\delta l\) is the element thickness. Thus the resistance change due to the presence of the particle is (Equation 3)

\[
\delta (\Delta R) = \delta R_0 - \delta R = -\frac{\phi_f a \delta l}{A^2} \left( 1 - \frac{\phi_f}{\phi_s} \frac{1}{1 - \phi_f/\phi_s a/A} \right)
\]

Assuming a constant current \(I\) across the aperture, the voltage pulse generated is \(I \Delta R\).

Theoretically, the response depends on the resistivity of the particle; however, this is rarely observed due to particle surface phenomena which render the particle resistivity practically infinite.\(^ {16}\) The quotient of the resistivity in Equation (3) is therefore negligible compared to unity, giving (Equation 4)

\[
\delta (\Delta R) = -\frac{\phi_f a \delta l / A^2}{1 - a / A}
\]

For spherical particles the change in resistance can be derived by integrating Equation (4), which yields (Equation 5)\(^ {15}\)

\[
\Delta R = \frac{8 \phi_f d^3}{3 \pi D^4} + \frac{4}{5} \left( \frac{d}{D} \right)^2 + \frac{24}{35} \left( \frac{d}{D} \right)^4 + \cdots
\]

where \(d\) and \(D\) are the particle and the aperture diameters respectively. As can be seen in this equation, the response increasingly deviates from linearity as particle size approaches aperture diameter. Errors due to neglecting diameter powers higher than \(d^3\) have been calculated for various shapes.\(^ {15,16}\)

Other theories have been proposed based on the Maxwell equation for the composite resistivity of a dilute suspension of insulating spheres in a conductive solution.\(^ {17-19}\) This can be written in the general form of Equation (6)

\[
\Delta R = \frac{\phi_f \rho F}{A^2}
\]

from which it is evident that the instrument response is proportional to the volume of the particle \(v\), modified by the function \(F\) which depends on particle shape and size. Although containing unequal powers of \(d\) and \(D\), most formulas proposed for \(F\) predict a constant value, i.e. a linear response for a particular aperture if the ratio \(d / D\) is much less than unity. However, significant deviations are indicated for large values of this ratio. Nonetheless, more recent experimental studies, carried out with constant-current instruments, showed linear particle responses up to 80% of the aperture diameter, for latex spheres.\(^ {21,22}\)

For grossly irregular shapes it has been recognized that this parameter has a considerable effect, and a self-calibration of the instrument (discussed later) is required which, nevertheless, will hold over the measuring range.
of the aperture.\textsuperscript{(21,23)} In any case, in practice, ratios of \(d/D\) exceeding 0.6 should be avoided as aperture blockage becomes too troublesome.

In addition to particle size and shape, the instrument response is also influenced by the inhomogeneous electrical field, or current density, in the aperture.\textsuperscript{(24)} In effect, the passage of the particles through regions where the field is not uniform will give rise to relationships between particle volume and resistance change that are more complex than that of Equation (6). A normalized pulse height topography in and near an orifice with a length (i.e. thickness) equal to its diameter is illustrated in Figure 4. As can be seen, pulse height and shape depend on the path of the particle through the orifice – for example, at the orifice inlet and outlet edges characteristic double-peak shapes are obtained, whereas those pulses from the center flow of the aperture possess a bell shape. Longer tubes generate nearly homogeneous fields in the central core of the aperture. Figure 4 also shows that the sensing zone of the orifice is not restricted to the orifice itself.

One way of eliminating these distorted pulses, and which is available in certain models, is to electronically edit them; that is, the pulses are examined and only those that conform to a reference pulse shape parameter (e.g. height to width ratio) are accepted.\textsuperscript{(25)} In some circumstances, this can also lead to a considerable loss of pulses which, in turn, is compensated by an improvement in the distribution resolution (discussed later). An alternative, that avoids the rejection of so much information, is to reshape pulses using mathematical equations.

\begin{equation}
    n = \frac{V_m}{V_z} \left(1 - \exp\left(-\frac{V_z N}{V_m}ight)\right)
\end{equation}

where \(V_z\) is the sensing zone volume and \(V_m\) the metered volume for each count. It should be emphasized that the effective volume of the sensing zone exceeds the physical

\textbf{2.3 Correction for Coincident Passages}

Ideally, the particles should traverse the aperture singly. However, there are inevitable probabilities of multiple-particle passages, which can result in two types of errors (Figure 5).

- **Primary coincidence** – two (or more) particles simultaneously present in the sensing volume may be counted as only one, depending on their proximity and on the instrument electronic resolution.
- **Secondary coincidence** – two very close particles, which individually originate pulses below a given height level, may collectively be sized as one particle well above that level.

As particle-size distributions should not be a function of concentration, the coincidence effect can be tested by comparing a distribution at one concentration to that at a lower concentration. Primary coincidence can be corrected mathematically, as explained below. Nevertheless the use of extremely dilute suspensions is recommended, as these will reduce both types of coincidence errors.

Several coincidence theories varying in complexity have been used.\textsuperscript{(26–28)} Most are based on the Poisson distribution of probabilities, in which the relationship between the true count \(N\) and the observed count \(n\) is

\begin{equation}
    n = \frac{V_m}{V_z} \left(1 - \exp\left(-\frac{V_z N}{V_m}\right)\right)
\end{equation}

\textbf{Figure 4} Pulse height distribution in and near an orifice of thickness equal to diameter. The maximum pulse height in the axial path is 96% of that in a homogeneous field. (Reproduced by permission of Wiley-VCH from V. Kachel, \textit{Part. Charact.}, 3, 45–55 (1986).)

\textbf{Figure 5} Effect of coincidence on count and size recorded.
edges of the aperture itself, as indicated in Figure 6 – in many cases $V_z$ is approximately 2.5 times the aperture volume.$^{(16,21)}$

Figure 6 Cross-sectional representation of the aperture, showing the effective sensing volume.

Equation (7) can be rearranged (Equation 8) as

$$N = -\frac{1}{\alpha} \ln (1 - an)$$

where (Equation 9)

$$\alpha = \frac{V_z}{V_m}$$

The unknown $\alpha$ can be eliminated by solving simultaneous equations obtained for different dilutions.$^{(28)}$

Usually simplifications of Equation (7) are utilized, as for example Equation (10)$^{(27)}$

$$n = N - cN^2$$

where $c$ is a constant related to the aperture size and sampling volumes, being determined experimentally.

The use of the Poisson distribution model to predict coincident losses has been questioned, especially for higher concentrations, and a more convenient algorithm has been proposed$^{(20)}$ that does not need a quadratic solution, as required by Equation (10).

Published data on coincident correction are sometimes contradictory and frequently depend on the instrument and on the aperture tube. However, providing that the concentrations are kept quite low (below 5% coincidence) almost all coincidence theories yield similar corrections. Most modern instruments make these corrections automatically.

Electronic pulse editing can also remove coincident passage pulses, as these have similar width and shape characteristics to edge-effect pulses.

### 2.4 Precision, Accuracy, Resolution and Sensitivity

Being a method frequently used as a reference, electrozone sensing should be capable of high precision, both in terms of repeatability and reproducibility, and accurate measurements. Its resolution and sensitivity should also be adequate to detect slight changes in particle-size distributions.

Although there is not much information on this subject in the literature, it is recognized that, for many particle-sizing techniques, repeatability is highly dependent upon sampling and/or dispersion of the powder and on the number of particles. For electrozone sensing measurements, a minimum count of 100,000 particles is recommended for obtaining good repeatability in the volumetric size distribution.$^{(13)}$ e.g. standard deviations less than 1–2 $\mu$m are expected for median sizes of moderately wide distributions of particles smaller than 100 $\mu$m. As for reproducibility, and despite written standards being available for this method, different operating and/or calibrating procedures may result in significant errors.$^{(30)}$

As these analyzers are usually calibrated with certified materials (as described later), the accuracy of the analysis is related to the precision of the calibration. This is governed essentially by the quality of the calibrating material and by the constancy of the calibration constant, both in time and over the measuring range – the accuracy of the calibration constant is usually about 0.5–1% for apertures below 100 $\mu$m.

Another important aspect of particle sizing is resolution, which is the ability to differentiate between two closely situated peaks or the ability to measure very narrow size distributions. The resolution of the early models was limited by the number of channels available. In modern multichannel analyzers, however, size distribution analyses may be performed using up to 256-channel resolution. In addition, data may be re-expressed as windowed data for even greater sizing resolution. Hence, the resolution now is normally limited by effects such as coincident particle passages and electronic field inhomogeneity. Several methods have been devised for improving the resolution of electrozone sensors, such as electronic pulse editing and the use of longer than conventional apertures. Pulse editing also enables particles to be resolved from baseline noise.$^{(25)}$ thus improving the quality of the measurements – in most situations where about 100 channels are used independently over the measuring range, a typical resolution of 0.1–0.5 $\mu$m is anticipated in the measurement range below 100 $\mu$m, which is high in comparison to many other techniques.

In the absolute sense, sensitivity can be defined as the number or volume of particles that differs significantly from blank electrolyte. For electrozone sensing the sensitivity is generally very good. Depending on the size of the particles, the sensitivity usually ranges from single particles (at larger sizes) to a few hundred (at small sizes) per size class and per milliliter of liquid sampled.
3 ANALYTICAL CONSIDERATIONS

As previously discussed, the amplitude of the pulses originated by the passage of the particles through the sensing zone is essentially proportional to particle volume, provided that certain conditions are fulfilled:

- particles should be adequately dispersed and homogeneously suspended in the beaker;
- the orifice diameter should be at least twice that of the largest particles to reduce blockage and nonlinear response;
- particle concentration should be low to minimize coincident passages through the orifice;
- particle diameters should give a signal above the noise level (which is normally obtained for \( d/D > 0.02 \)).

The aim of this section is to supply some information regarding operational procedures so that these conditions are accomplished.

3.1 Sample Preparation

The quality of any particle-size analysis result is greatly influenced by the accuracy and reproducibility of the sampling and dispersing techniques. Generally, the quality of the measurement depends on how representative the sample is of the bulk from which it is drawn. In many cases the analyst is presented with laboratory material, the sampling of which he has no control over. Then there is often the need to reduce the laboratory sample to quantities suitable for particle-size analyses, it being therefore indispensable to ensure the homogeneity of the material throughout subdivision. Various devices have been developed for taking samples from the bulk of a powder and for splitting primary samples to smaller ones.\(^{10,31}\) The spinning riffler has been widely used for this purpose. In this instrument, the powder delivered from a hopper by a small vibratory feeder falls on to a succession of receivers mounted on a rotating table. Sampling an agitated suspension with a syringe or pipette is also a good method for the preparation of very small measurement samples (like those required for electrozone sensing). However, for coarse powders (>20\( \mu m \)), concentration gradients and particle segregation due to settling may lead to selective sampling. Suspension samplers with multiple capillary tubes have been designed to eliminate these errors. Whichever method is adopted, it is recommended that its efficiency is checked.

The material under test should be well dispersed because the presence of agglomerates generates untrue size distributions and is often connected with poor repeatability of the results. In some cases the test is related to the state of dispersion in an application, so that the quantity of agglomerates is the reason for the measurement. Ideally, the following requirements have to be met:

- the solid particles should exist in the suspension individually (i.e. free of agglomerates);
- the dispersion state should not be modified during the time of the analysis.

If a dry powder is to be used for preparation of a suspension, it should be spatulated with a few drops of a suitable dispersant and slowly diluted with the electrolyte solution. Further dispersion with ultrasonic energy is normally used, except for very fragile or biological materials. It is always important to indicate clearly the specific protocols adopted for both sampling and dispersion.

A microscopic examination of the suspension should be carried out prior to the analysis, to check the degree of dispersion and to estimate the size range of the particles. This is necessary to select the most adequate aperture tube.

The stability of the dispersion during the analysis time should be checked by comparing repeat analyses, using a multichannel counter if possible. This type of instrument is particularly useful to study this phenomenon, owing to the rapidity with which the analyses can be performed. Table 1 shows some symptoms of instability and its main causes.\(^{11,32}\)

Suitable agitation should also be assured by adjusting the stirrer speed to maximum effect without entraining air bubbles.

3.2 Choice of Electrolyte Solution

Electrolytes for electrozone measurements must have suitable electrical conductivity and physicochemical neutrality towards the particles. A list of the most useful electrolytes as well as dispersants and their applications is usually supplied by the instrument manufacturers and

\(^a\) + denotes count increase, – denotes count decrease, 0 denotes no change.
is also available in the literature. For a given material, the electrolyte used must not cause the particles to agglomerate, react, dissolve, disintegrate, shrink, or swell.

Aqueous media are widely employed because the great majority of materials are water insoluble or only slightly soluble. An electrolyte solution of about 10 g L$^{-1}$ sodium chloride in water or 50 g L$^{-1}$ hydrated trisodium orthophosphate solution is often used because the conductivity is adequate. In some cases, chloride ions can inhibit dispersion and alkaline phosphates present more advantages. In general, the addition of an effective wetting agent or dispersant (directly to the sample, as explained above) greatly helps in dispersing the sample. The optimum choice of dispersant is often a matter of trial and error, with microscope examination being usual – particular attention should be paid to any eventual negative effects (such as dissolution). When the particulate material is sparingly soluble in water, the electrolyte should be first saturated with that material and filtered for usage. The saturated solution should not be left standing and the analysis should be performed immediately.

Alternatively, organic media (such as alcohols, ketones and chlorinated hydrocarbons) are needed for water-soluble materials, including salts, sugars, and foodstuff. Other materials may already be suspended in media that are immiscible with water. Polar organic liquids having dielectric constants greater than 10 with readily ionized materials such as lithium chloride or ammonium thiocyanate are widely used in both cases.

To measure small particles (≤1 µm) with small apertures, the use of an electrolyte with a very high conductivity is recommended to increase the signal-to-noise ratio – a possible solution would be to use 60–80 g L$^{-1}$ sodium chloride in water instead of 10 g L$^{-1}$. However, problems may then be encountered in suspending large and/or dense particles that tend to settle in the dispersion beaker and/or in the tube behind the aperture. The addition of a thickening agent to increase the electrolyte viscosity (e.g. glycerol or sucrose) together with the use of a round-bottomed beaker fitted with baffles and special stirrer paddles favor the homogeneity of the suspension.

For highly accurate particle-size analyses, electrolytes must be virtually free of particles. The electrolyte solutions should therefore be carefully filtered before use (0.45 µm or 0.22 µm membrane filters are commonly employed) and the background counting should not exceed the values recommended in the instrument manuals (see section 4.3).

As part of the normal operating procedure, a background count in clear electrolyte is always carried out and recorded, and later subtracted from the sample-plus-background data to obtain the true particle counts.

### 3.3 Orifice Tube Selection

Most distributions of particulate materials sized by electrical sensing have equivalent diameters in the range between 0.5 µm and 150–250 µm. Some commercial instruments are capable of measuring particles up to 1200 µm and experimental designs have provided results down to 0.1 µm. However, broad size ranges can only be covered by using multiaperture analyses, as described later.

The effective size range that a typical orifice can measure is from about 2% to 60% of its orifice diameter, which corresponds to a size span of 30:1 by diameter. The lower limit is normally determined by the electrical noise which prevents the pulses generated by the smaller particles from being discernible. This noise may come from the electronic circuitry of the instrument, from surrounding equipment, or from particles in the sample that pass through the sensitive zone of the aperture without entering it. A special case may occur with sedimented particles that accumulate behind the aperture during analysis. They can be diagnosed by performing a background analysis after sample measurement without clearing the aperture tube.

The upper limit is essentially dictated by the aperture blockage which, for nonspherical particles, is mainly governed by their largest size, and by the increasing nonlinearity of the response (discussed above). There is experimental evidence that some models produce accurate measurements up to 70–80% of the aperture sizes.

Determination of the largest and smallest particles present in the sample is usually made by microscope inspection, by trial-and-error procedure with various aperture tubes, or by some previous knowledge about the sample.

The apertures available span from 15 µm to 2000 µm. The use of the large apertures is controlled by the ability to suspend the particles uniformly in the beaker. Analyses with apertures less than 50 µm are more sensitive to noise and require special care with the experimental conditions – the strength and cleanliness of the electrolyte solution is crucial and any atmospheric contamination or electrical interference (internal or external) should be avoided as they can result in false counts.

Particles larger than recommended for a given aperture, or that tend to agglomerate, may cause aperture blockage. An aperture projection system, normally incorporated in the instrument, allows the operator to visualize any blockage or partial blockage. Blockages can also be detected by changes in the pulse pattern displayed on the oscilloscope, when available. In most cases, the blockages are readily cleared by backflushing or by brushing the particles off the orifice with a special brush (bent to a 90°
angle at the metal end and with the hairs cut short). However, certain analyzers have automatic blockage detection and clearance of the sensing orifice.\(^3\)

Although the majority of materials encountered fall within a size range that can be analyzed using only one orifice, samples with a very wide size distribution require the use of two (or more) apertures. For example, over 2% by volume of the particles fall in the smallest size interval, if a bimodal size distribution with one mode essentially below the threshold is expected or if a significant mass-balance deficit is encountered, it is then advisable to use the multiaperture method\(^{11}\) to obtain the full size distribution. The ratio of the orifice diameters should not exceed 5 : 1 to ensure that the ranges covered by each tube are allowed to overlap by several micrometers. In general, multitube operations require experienced operators and extra time because larger particles have to be removed by sieving or partial sedimentation, before using smaller aperture tubes. Furthermore, if the particle-size curves (number versus diameter) obtained with the two (or more) apertures do not overlap (due to incorrect calibration or loss of particles during separation), the procedure has to be repeated. Data blending can be performed manually or by software.

### 3.4 Data Processing

The capabilities of particle sizers have been immensely improved by increases in computer power and the ability to record and handle huge amounts of data in very short times has made virtually all measurements possible. The problem now is that instruments which measure the same particle property, and use essentially the same analytical settings with which the data was obtained can also be saved, allowing easy retrieval for future analyses. Numerous options are now available to present the data in tabular form or graphically (cumulative or differential curves, undersize or oversize), using logarithmic or linear scales. The operator is able to select the presentation form and sequence for a particular report from a vast list of preferences.

Statistical analysis of the size distribution as a function of diameter, volume or surface area, including mean, median, mode, standard deviation, skewness, and kurtosis, is normally accessible. In some cases users can electronically isolate subpopulations of interest and further expand the measurement resolution.

Data saving also enables the plotting of multiple files on the same graph for comparative studies together with the corresponding statistics. Extrapolations to estimate the percentage below the detection limit may also be possible automatically, if neither a second aperture is used to complete the analysis nor a mass balance is performed (as explained later).

### 4 INSTRUMENT CALIBRATION AND VALIDATION

As the response of the electrical sensing zone method is essentially proportional to the volume of the particles, the pulse height provides a relative scale of particle volumes. Calibration involves converting the arbitrary pulse height into spherical diameter, that is, to determine the calibration constant, according to Equation (11)

\[
K_d = \frac{d}{\sqrt{T}}
\]

where \(K_d\) is the calibration constant based on diameter, \(d\) is the equivalent volume diameter, and \(T\) is the pulse height (threshold value).

Calibration can be performed in two different ways:

- Latex calibration – using narrowly distributed spherical latex particles.
- Self-calibration – utilizing the particles of the material under test.

Self-calibration, also called mass calibration or mass integration, is recommended in the British Standard\(^{11}\) as a primary calibration procedure. It is superior to latex calibration because it eliminates any possible errors caused by shape, porosity or conductivity effects of the material to be analyzed. This procedure is therefore more direct and traceable; however, it is not used routinely, so it requires a more elaborate and consequently more time-consuming procedure. In addition, it must be ensured that all particles fall well within the size range of the aperture and no count losses occur in the instrument.

### 4.1 Latex Calibration

Latex calibration is commonly performed with latex samples which have certified modal, median and/or mean
sizes. Poly(styrene divinyl benzene) latices are particularly recommended for this purpose as these particles are durable and will not change size upon immersion in most electrolyte solutions (special precautions should be taken when using organic electrolytes because the latices may swell or dissolve in some of these liquids). The latex particles should have a mean diameter between 5% and 20% of the aperture diameter, and are obtainable from several sources including manufacturers of electrical sensing zone equipment.

In single-channel models, the calibration is often performed using the so-called half-count method. This consists basically of determining the counts corresponding to threshold levels equal to 0.5\(T\) and 1.5\(T\), where \(T\) is the average height of the pulses visualized on the oscilloscope. The threshold value corresponding to the count which equals the average of the above counts is the one to be used in Equation (11) to evaluate the calibration constant \(K_d\), knowing the singlet number median diameter of the latex. More sophisticated particle counters, allowing multichannel analyses, can be more rapidly calibrated by relating the mode of the generated size distribution to the latex number mode.

The calibration constant, which is valid for each aperture tube–electrolyte pair, should be checked periodically and the results recorded to monitor any significant long-term deviation.

### 4.2 Self-calibration

Although latex calibration is more widely used, the most accurate method is self-calibration. In this method, a size fraction of the material being examined, preferably not exceeding 10:1 by particle diameter, is diluted to an exactly known mass concentration in electrolyte solution. The volume of the particles in a metered volume of suspension \(V_p\) will be given by Equation (12)

\[
V_p = \frac{V_m W}{\pi V_T \rho_s} \quad (12)
\]

where \(V_m\) is the metered suspension volume, \(V_T\) is the total suspension volume, \(W\) is the total mass of the powder, and \(\rho_s\) is the particle density.

This volume can also be obtained by measuring the particle-size distribution, resulting in Equation (13):

\[
V_p = \frac{\pi}{6} \sum \Delta n_i d_i^3 \quad (13)
\]

where \(\Delta n_i\) is the number of particles in a size interval \(i\) and \(d_i\) is the mean diameter (based on the mean volume) for that size interval.

Substituting Equation (11) in Equation (13) results in Equation (14),

\[
V_p = \frac{\pi}{6} K_d^3 \sum \Delta n_i T_i \quad (14)
\]

where \(T_i\) is the average threshold (corresponding to \(d_i\)).

If all the particles have been counted over the whole measuring range, Equations (13) and (14) can be compared to give Equation (15):

\[
K_d = \frac{6 V_m W}{\pi \pi V_T \rho_s} \frac{1}{\sum \Delta n_i T_i}^{1/3} \quad (15)
\]

This equation is often presented in the literature in the alternative form (Equation 16)

\[
K_d = \frac{6 V_m W}{\pi \pi V_T \rho_s} \frac{1}{\sum \Delta n_i \bar{V}_i}^{1/3} \quad (16)
\]

where \(\bar{V}_i\) is not always well defined and can be incorrectly identified with a real volume. Real volumes can only be obtained if a prior calibration has been performed. A more suitable form of Equation (16), in terms of volume values, has been proposed (Equation 17) as

\[
K_d = K_{d_i} \frac{V_m W}{V_T \rho_s} \frac{1}{\sum \Delta n_i \bar{V}_{0,i}} \quad (17)
\]

where \(K_{d_i}\) is the initial estimate of the calibration constant (which could be the latex calibration constant) and \(\Delta n_i \bar{V}_{0,i}\) is the total volume of particles computed by the instrument when using \(K_{d_i}\).

The difference between the particle-size distribution obtained by using the latex and the self-calibration constants were found to be negligible for moderately aspherical particles. However, the self-calibration method is more fundamental and should be used to remove any doubt, especially when dealing with highly irregular, porous, or conductive particles, for which appreciable differences have been reported.

Self-calibration requires great accuracy in determining the particle concentration in the suspension and a counting efficiency of 100% in order to obtain a precise value for the measured volume. The chosen method of calibration should be specified when results are reported.

### 4.3 Instrument and Method Validation

The first check on instrument, aperture, and electrolyte occurs in the blank (background) measurement. Background counts should be lower than the values given in Table 2.
### Table 2 Maximum acceptable background counts

The second check should come from the monitoring exercise of the calibration constant – the value of the calibration constant should lie within the limits for 95% confidence level relative to the predetermined mean values.\(^{13}\)

Finally, a *mass-balance* procedure\(^{10,11,42}\) is also recommended. This procedure is similar to that used for self-(or mass) calibration. Basically, it balances the volume of the particles measured by the instrument in a metered volume of suspension (Equations 13 or 14) with that calculated from the particle concentration (Equation 12). The ratio of these two values gives the fraction of the powder that is accounted for in the measurement. If there are no other particles present in the sample, there should be less than 3% deviation from 100%. Alternatively, this method may also be used to quantify the fraction of particles missed in the measurement, for example because their size is below the lower limit of the aperture. It is evident that the measurement results should be as precise and accurate as possible. Potential error sources and procedures to eliminate them have been discussed elsewhere.\(^{42}\)

### 5 SPECIAL APPLICATIONS

Electrozone sensing, despite being a long-established and widely used method, is still the subject of study and development. Several approaches have been investigated to improve the resolution of electrozone sensors to measure closely sized particles. Increased interest in narrow and ultranarrow (coefficient of variation (CV) less than 2% for diameter) size-range materials, such as biological cells, polymer latices (used as size calibration references), and man-made monodisperse materials (for use as chromatography column packings), has demonstrated the need to improve the resolution of standard orifices. The signal produced when a particle passes through a conventional aperture depends on its size and other physical characteristics, and also on its path near and through the aperture, mainly due to the aperture electric field inhomogeneity.

As depicted in Figure 7, particles passing close to the edge of the orifice generate pulses somewhat higher and considerably longer (frequently M-shaped) than they should be, thus reducing the accuracy of the method. This does not affect the analysis of powders having a wide size distribution (as for most powders of industrial interest) but causes overestimated distributions of nearly monosized materials, which are typically skewed towards the coarser sizes and often present an additional peak.\(^{24,43,44}\) The two procedures that have been suggested to improve this situation are electronic pulse editing (already discussed) and *hydrodynamic focusing*, where particles are directed along the central axis of the aperture.\(^{45–47}\)

Hydrodynamic focusing (Figure 8) has been the most successful because it is straightforward, prevents particles from passing through regions of inhomogeneous electrical field and also eliminates circulation of particles close to the orifice (which normally results in countable pulses).

A system similar to hydrodynamic focusing has also been applied to measuring fibers (which are particles with a very low aspect ratio) using electrozone sensing.\(^{48}\) Fiber measurement is of paramount importance in the pulp and paper industry, as fiber length and diameter relate directly to paper properties. The Kajaani FS-200,

![Figure 7 Influence of particle flow path on pulse shape.](image-url)

![Figure 8 The hydrodynamic focusing principle.](image-url)
an automated optical analyzer based on the ability of cellulose fibers to change the direction of polarized light, has been extensively used for sizing pulp fibers. More recently, improvements in computer-based image processing have also led to the development of fiber analyzers that provide rapid and operator-independent measurements. All these automated analyzers comprise a configuration that allows fiber alignment in the measuring zone. As long as fibers flow axially through the aperture, it has been shown that if a prior calibration is performed with fibers of constant length, the instrument response is proportional to the fiber cross-sectional area, from which fiber diameter can be calculated. Fiber lengths can also be evaluated to some degree of accuracy by measuring the pulse duration instead of pulse amplitude.

Other modifications relate to real-time analyses, that are not possible with the traditional off-line procedures and imply either on-line or in-line measurements. The major difference between off-line and in-line measurement is that in the latter sampling and analyzing are closer both in time and space. In addition, on-line measurements reduce the sampling step even more by inserting a probe into the stream, thus allowing localized measurements.

Although this increase in automation usually means a loss of accuracy, the benefits are considerable. For example, the data may be passed to a control program enabling process monitoring. It has been reported that electrozone sensors have been adapted for real-time processing.

In the pharmaceutical industry electrozone analyzers are used not only to assess the drug particle size but also to study the disintegration of tablets, particle swelling, and dissolution rates—the size of the drug particle determines its dissolution rate and, ultimately, the rate of absorption.

The limitations of the electrozone method mainly relate to particle characteristics. For example, particle porosity may influence the response of electrical sensing devices. This is basically because when the pores get filled by the suspending medium they may not be counted as particle volume, resulting in measured volumes considerably smaller than the real particle envelope size. There are also some indications that the wetting properties of the electrolyte solution could also play an important role in the obtained data. A number of researchers have investigated the effect of porosity by filling the pores with an inert material and have even suggested that the pore volume could be estimated from the differences in sizing raw and filled-pore samples. However, by not assuming that the specific resistance of the particles (nonconductive as well as conductive) is practically infinite, it has been shown that the apparent resistance of some conductive particles (e.g. carbon, palladium, and nickel) are dependent on the voltage drop over the particle when it passes the orifice. Critical values have been determined, above which particles may act as a conductor causing large deviations; therefore, adequate conditions must be established beforehand to ensure reliable measurements. Finally, there is evidence that the response of electrozone sensors, besides being a function of particle volume, is also affected by its shape. Experiments carried out with large-scale versions of electrical sensing instruments indicated that shape has a constant effect which can be eliminated with self-calibration.

6 COMMERCIAL EQUIPMENT

The majority of the electrical sensing zone-based instruments currently in use were manufactured by Coulter Electronics, and by Particle Data under the trade name of Elzone™. Coulter™ and Elzone™ are presently marketed by Beckman Coulter and by Micromeritics respectively. The most widely used models are the Coulter Model TAI, the Coulter ZM and the Elzone™ series 180. Although many of these models are still in use, they are not in current production; the descriptions below are confined only to those models that are commercially available.

The Coulter models in current production are the Z series and the Coulter™ Multisizer Ill. The Z series was designed to be easy to use and consists of the Z1 single threshold, the Z1 dual threshold and the Z2. The Z1 is fundamentally a particle counter, whereas the Z2 is a particle counter and size analyzer that works in the 1–120 µm range. The latter records particle data in 64, 128, and 256 channels, enables the operator to view the data, allows statistical treatment of the results, and permits automatic run and an average of up to 10 replicates. The Coulter™ Multisizer operates in the overall size range 0.4–1200 µm at up to 5000 counts per second and also enables the selection of the number of size classes (channels), from 64 to 256. Built-in cursors permit the isolation of subpopulations, thus increasing the instrument resolution to 25 000 channels. Editing facilities are also available to remove the most distorted pulses which, as discussed before, improves the accuracy of the analysis of narrow-sized range materials. Dedicated personal computer software enables data processing and storage, size distribution statistics, run overlays and averages, multivariate overlapping and data export (Figure 9).

At present, Micromeritics markets the Elzone™ 5380 and 5382 particle analyzers, both performing complete counting and sizing capability in the range 0.4–1200 µm. These analyzers are operated via an external personal
computer control module and both perform high-speed and multichannel analyses. The main difference between them is that the model 5380 (illustrated in Figure 10) has one analysis station whereas the 5382 has two. In addition, the latter has automated valves which highly reduce the operator intervention. A set of macro commands allows repetitive analyses and the software enables sample information and collected data to be saved which can be presented in tabular and graphic form and plot overlays. These models are capable of autoblockage detection and clearance at the sensing orifice.

Field-flow Fractionation in Particle Size Analysis

Josef Janča
Université de La Rochelle, France

1 Introduction

Field-flow fractionation (FFF) is an analytical methodology suitable for the separation and characterization of macromolecules within a wide range of molar masses, and for particles in submicrometer and micrometer ranges. The separation is based on the action of effective physical or chemical forces across the separation channel. The field forces interact with the separated species and concentrate them at the appropriate position inside the channel. The resulting concentration gradient induces an opposite diffusion flux. This process leads to a quasi-steady-state distribution of the affected sample components across the channel. The velocity of the longitudinal flow of the carrier liquid also varies across the channel. A parabolic flow velocity profile is usually established inside the channel. The components of the separated sample are transported in the longitudinal direction inside the channel at different velocities, depending on the transverse positions of the zones of the sample components within the flow of the carrier liquid.

The separation is performed in one liquid phase. This is of fundamental importance for the fractionation and particle size analysis of biological samples, which can be sensitive to the type and intensity of the interaction with the surfaces and can denature. Steady-state inside the channel is usually reached within a short time due to a small channel thickness. The simplicity of the channel construction permits an accurate description of the separation processes.

The field strength can be controlled over a wide range. Many operational variables in FFF can be manipulated during the experiment by suitable programming.

Accurate analytical results can be obtained from FFF by correct treatment and interpretation of the experimental data. If the relationship between the retention parameters and the characteristics of the separated particles is known, or can be predetermined by using an appropriate calibration procedure, the characteristics of an unknown analyzed sample can be evaluated quantitatively. The particle size distribution (PSD) of the analyzed sample then is determined from a fractogram.

1 INTRODUCTION

FFFFF is relatively new but important analytical methodology suitable for the separation and characterization of macromolecules over a wide range of molar masses, starting at several thousand grams per mole up to perhaps $10^{18}$ g mol$^{-1}$, and especially for particles in the submicrometer and micrometer ranges. Very few, if any, of today’s separation techniques possess such flexibility. Its development since the late 1960s into a variety of specific methods and techniques represents an important contribution to the science and technology of analytical separations of large molecules and particles.

The separation in FFF is based on the action of effective physical or chemical forces (e.g. temperature gradient, electric, magnetic, gravitational, or centrifugal forces, chemical potential gradient, etc.) across the separation channel. The field forces interact with the separated species and concentrate them at the appropriate position inside the channel. The resulting concentration gradient induces an opposite diffusion flux. This process leads to a quasi-steady-state distribution of the affected sample components across the channel. The velocity of the longitudinal flow of the carrier liquid also varies across the channel. A parabolic flow velocity profile is usually established inside the channel. The components of the separated sample are transported in the longitudinal direction inside the channel at different velocities, depending on the transverse positions of the zones of the sample components within the flow of the carrier liquid.
depending on the transverse positions of the zones of the sample components within the flow of the carrier liquid.

The general principle of FFF is demonstrated in Figure 1. A carrier liquid is pumped through the sample injector to the fractionation channel and leaves the separation system after passing through the detector, which allows the monitoring of the eluting species and the recording of the fractograms.

Two specific mechanisms—polarization(1) and focusing(2)—lead to the formation of different concentration distributions across the fractionation channel. The components of the fractionated sample are thereby differently compressed onto the accumulating wall of the channel, or focused at different positions, as shown by details (A) and (B) in Figure 1. Despite their principal differences, polarization and focusing FFF have many common characteristics such as the experimental procedures, instrumentation, data treatment, and the range of potential applications. The separation is performed in a single liquid phase. A stationary phase of large surface area (typical for a chromatographic column of comparable separation capacity) is absent in all FFF separation channels, regardless of the particular method or technique applied. This feature is of fundamental importance for the fractionation and particle size analysis of biological samples, which can be sensitive to the type and intensity of the interaction with the surfaces and can denaturate. The inner surface of the FFF channel plays no active role in the separation process and it can be deactivated so that undesirable interactions are minimized. Especially in focusing FFF methods, only a very small part of the separated species comes into direct contact with the channel walls. Steady-state inside the channel is usually reached within a short time due to a small channel thickness. The simplicity of the channel construction permits an accurate description of the separation processes.

The strength of the field can be controlled over a wide range in order to manipulate the retention. Consequently, in polarization FFF methods, the complete passage of a particular sample component through the channel represents the lower retention limit, whereas the retention is total when the given component is completely compressed against the channel wall. Retention ratio, as defined by Equation (26), from zero to approximately 0.02 comes into account in practice for polarization FFF methods. With focusing FFF methods, the retention is even more versatile. Many operational variables in FFF can be manipulated during the experiment by a suitable programming, although not all have been applied experimentally.

Any displacement of the separated species depends on the existence of the driving forces. The processes which cause the formation of concentration gradients vary with the character of the field. Accordingly, the applied field determines the individual polarization FFF methods. However, the focusing process is always related to the existence of the gradient of the effective forces. Only when the driving forces are dependent on the position across the channel, and vanish at a given position, can focusing occur.

As a result, polarization FFF methods are classified with regard to the nature of the main field applied, whereas focusing FFF methods are classified by considering the combination of various gradients and fields, thereby emphasizing the focusing processes.

The historical background of this modern separation methodology can be seen, for example, in the recovery of gold by panning, or of other metals and minerals as demonstrated in the middle-ages rendition in Figure 2.(3) The gravitation and the stream of running water were used to separate the gold particles from other particulate material (soil, clay, sand, etc.). The use of this principle dates back to some 5000 years BC.

Some formerly proposed separation methods are also based on the combined action of field forces and hydrodynamic flow. The fractionation of proteins by combined electrophoresis-convection described by Kirkwood(4) in 1941 and extended in 1952 by Kirkwood and Brown(5) to a combination of diffusion-convection, or thermal diffusion combined with free thermal convection applied in Clusius and Dickel(6) thermogravitational columns, can be also considered as precursors of FFF.
However, the true beginnings of FFF can be attributed to Giddings\(^1\) who described the general concept as well as polarization FFF. The aerostat shown in Figure 3, created by Joseph and Etienne Montgolfier,\(^7\) is a phenomenological predecessor of the generic invention of the focusing FFF.\(^2\) More specific or generalized separation mechanisms were subsequently proposed and exploited such as steric FFF\(^8\) for the polarization FFF mode or generalized isoperichoric focusing FFF\(^9,10\). The term ‘isoperichoric’ was introduced by Kolin\(^11\) and is derived from the Greek language where *isos* means ‘equal’ and *perichoron* means the ‘environment’. This term therefore means that the focusing forces are generated by the difference between the local effective property of the dispersing carrier liquid and the corresponding parameter of the focused sample component.

Polarization FFF methods utilize the exponential concentration distribution that forms for each sample component across the channel, with the maximum

Figure 2 Middle-ages device for the recovery of gold particles and minerals from sand, clay, and soil blends by combining sedimentation and quasihorizontal movement of water, accompanied by vigorous manual stirring of the mud cake.

Figure 3 Aerostat of Montgolfier’s brothers invention in 1783.
concentration at the accumulation wall. This is the consequence of the constant and position-independent velocity of the transverse migration of the affected species due to the field forces. This concentration distribution is combined with the velocity profile formed in the flowing liquid.

Focusing FFF methods make use of the transverse migration of each sample component under the effect of the driving forces that vary across the channel. As a result, the sample components are focused to positions where the intensity of the effective forces is zero and are transported longitudinally with different velocities according to the established flow velocity profile. The concentration distribution within a zone of a focused sample component can be described by Gaussian or similar distribution functions.

Accurate analytical results can be obtained from FFF by applying the correct treatment and interpretation of the experimental data. If the relationship between the retention parameters and the characteristics of the separated particles is known, or can be predetermined by using an appropriate calibration procedure, the characteristics of an unknown analyzed sample can be evaluated quantitatively. The PSD of the analyzed sample then is determined from a fractogram.

2 PRINCIPLES AND THEORY

The FFF methodology is based on the simultaneous action of the effective field forces and of the liquid flow inside a separation channel operating on the fractionated species. The channel thickness is small, usually between 50 and 500 µm; the ratio of the channel width to its thickness is typically between 20 and 200; the usual length is from 10 to 100 cm. The mutual orientation of the field forces and of the carrier liquid flow is perpendicular. The liquid flows in the direction of the channel longitudinal axis and the field forces act across the channel (Figure 1). The sample is injected into the channel as a short pulse or as a continuous stream carried by the flow. The field generates the driving forces which induce a mass flux of the sample components. A concentration gradient of each sample component is formed across the channel. This concentration gradient induces an opposite flux due to the diffusion, Brownian motion, repulsive interactions, etc. As a result, a steady-state concentration distribution of each sample component across the channel is established. Simultaneously, a flow velocity profile is formed across the separation channel. The sample components are transported in the direction of the flow at different velocities, depending on the position of the centers of gravity of their concentration distributions in the flow velocity profile. Consequently, they leave the channel at different elution times and are thus separated. Two distinct cases, A and B in Figure 1, correspond to the two different separation mechanisms, polarization and focusing, resulting in zones either differentially compressed at the accumulation wall or focused at different levels in a free volume of the channel. Although the separation and accompanying processes are carried out in a three-dimensional channel, the following two-dimensional model is a fair approximation of the reality.

The driving forces can be generated by a single field as well as by the coupled action of two or more different fields. Polarizing and focusing forces can operate simultaneously, resulting in a complex mechanism of separation. The field force, \( F \), and consequently the migration velocity, \( U \), are independent of the position in the direction of the \( x \) axis in polarization FFF (Equation 1):

\[
F \neq 0 \text{ and } U \neq 0 \text{ for } 0 < x < w \tag{1}
\]

Here \( w \) is the distance between the main channel walls in the direction of the \( x \) axis, with \( x = 0 \) at one wall of the channel. Dispersion processes act against field induced flux until the steady state is reached. The steady-state concentration distributions of the affected sample components across the channel are exponential only if ideal polarization FFF is effective.

However, it holds for the \( x \) axis-dependent direction of the field force in focusing FFF (Equations 2–5):

\[
F = F(x) \text{ and } U = U(x) \text{ within } 0 < x < w \tag{2}
\]

\[
F(x) = 0 \text{ and } U(x) = 0 \text{ for } x = x_{\text{max}} \text{ with } 0 < x_{\text{max}} < w \tag{3}
\]

\[
F(x) > 0 \text{ and } U(x) > 0 \text{ for } x < x_{\text{max}} \tag{4}
\]

\[
F(x) < 0 \text{ and } U(x) < 0 \text{ for } x > x_{\text{max}} \tag{5}
\]

Here the coordinate \( x_{\text{max}} \) corresponds to the position at which the concentration distribution of a sample component across the channel attains its maximal value. Each sample component is focused in the direction of the \( x \) axis around its proper \( x_{\text{max}} \) position. The dispersive forces, in this case, act in both opposite directions from the \( x_{\text{max}} \) position until the steady state is reached. The resulting shape of the concentration distribution is close to the Gaussian distribution function.

Selective transport of the separated sample components and related dispersion phenomena are the main processes that characterize any separation method. A sample component undergoing the effect of the field forces in FFF is displaced in the moving carrier liquid by the combined action of the flow and field applied. The resulting velocity vector \( \mathbf{v} \) can be decomposed into two perpendicular vectors: \( \mathbf{U} \), induced by the applied field, and a flow-induced
component \( v \) (Equation 6).

\[
\mathbf{u} = \mathbf{U} + \mathbf{v} \quad (6)
\]

The total flux of a sample component \( j \) can also be written as a sum of transversal flux in the direction of the \( x \) axis and of axial flux in the direction of the longitudinal \( y \) axis (Equations 7–9):

\[
j = j_x + j_y \quad (7)
\]

\[
j_x = -D_x r_x \frac{\partial c}{\partial x} + U c \quad (8)
\]

\[
j_y = -D_y r_y \frac{\partial c}{\partial y} + v c \quad (9)
\]

where \( D_{x,y} \) and \( r_{x,y} \) are the diffusion coefficients and the unit vectors, respectively, and \( c \) is the concentration.

The transverse and longitudinal transports can be considered separately, in a first approximation. However, the longitudinal flow of the carrier liquid permanently perturbs the transverse concentration distribution. The deviation from the steady-state can be characterized by the equilibrium departure term \( \epsilon \) (Equation 10):

\[
c = c^* (1 + \epsilon) \quad (10)
\]

where \( c \) and \( c^* \) are the actual and steady-state concentration distributions, respectively.

### 2.1 Polarization Mechanism

The polarization mechanism is characterized by the transversal flux at equilibrium (Equation 11).

\[
D_x r_x \frac{\partial c}{\partial x} - U c = 0 \quad (11)
\]

The solution of Equation (11) is the exponential concentration distribution of the sample component across the channel (Equation 12):

\[
c(x) = c(0) \exp \left( \frac{r_x U}{D} x \right) \quad (12)
\]

With respect to the positive direction of the \( x \) axis, the vector \( \mathbf{U} \) is negative. Consequently, Equation (11) can be rewritten in the form of Equation (13):

\[
-D_x \frac{\partial c}{\partial x} - U c = 0 \quad (13)
\]

As a result, Equation (12) can be rewritten in scalar form as (Equation 14):

\[
c(x) = c(0) \exp \left( \frac{-x U}{D} \right) \quad (14)
\]

Defining the mean layer thickness as \( l = D/U \) gives Equation (15):

\[
c(x) = c(0) \exp \left( \frac{-x}{l} \right) \quad (15)
\]

For strongly polarized concentration distributions, the mean layer thickness measured from the accumulation wall, is practically equal to the position of the center of gravity of the concentration distribution in the direction of the \( x \) axis.

### 2.2 Focusing Mechanism

The flux of a sample component in the direction of the \( x \) axis is expressed by Equation (16):

\[
j_x = -D_x r_x \frac{\partial c}{\partial x} + U(x) c \quad (16)
\]

Equation (16) differs from Equation (8) by the \( x \) axis-dependent velocity \( U(x) \). At the steady state Equation (17) holds:

\[
D_x r_x \frac{\partial c}{\partial x} - U(x) c = 0 \quad (17)
\]

The velocity vector \( \mathbf{U}(x) \) is either positive or negative regarding the orientation of the \( x \) axis and relative to \( x_{\text{max}} \). The force \( F(x) \), acting on one particle undergoing the focusing can be written in scalar form as Equation (18):

\[
F(x) = U(x) f \quad (18)
\]

The friction coefficient is defined by Equation (19):

\[
f = \frac{k T}{D} \quad (19)
\]

where \( k \) is the Boltzmann constant, \( T \) is the absolute temperature, and \( D \) is the diffusion constant. Then Equation (20) holds:

\[
\frac{dc}{dx} = -\frac{F(x) c}{k T} \quad (20)
\]

The focusing force can be approximated by Equation (21):

\[
F(x) = \left( \frac{df(x)}{dx} \right)_{x=x_{\text{max}}} (x-x_{\text{max}}) \quad (21)
\]

where \( (df(x)/dx)_{x=x_{\text{max}}} \) is the driving force gradient, assumed constant near \( x_{\text{max}} \). The solution of Equation (20) is given by Equation (22):

\[
c(x) = c_{\text{max}} \exp \left( \frac{1}{2 k T} \left( \frac{df(x)}{dx} \right)_{x=x_{\text{max}}}(x-x_{\text{max}})^2 \right) \quad (22)
\]
which is the Gaussian concentration profile of a single focused component.

A completely different approach,\(^{12,13}\) which takes into account the actual shape of the transverse gradient of the focusing forces, leads to accurate solution without an a priori assumption of the constancy of the gradient in the domain of the focused zone. The details are given in the section on focusing methods and techniques.

### 2.3 Flow Velocity Profiles

The separation is performed inside a narrow channel, usually composed of two highly polished plane and parallel surfaces between which a spacer of given constant thickness is clamped. Such a design results in a rectangular cross-section channel. Other shapes of the channel cross-section result in different hydrodynamic conditions and various flow velocity profiles. Velocity distribution in the isothermal, isoviscous flow of a Newtonian carrier liquid flowing between two parallel infinite planes under laminar conditions and not affected by a field is parabolic and described by Equation (23),

\[
v(x) = \frac{\Delta P x(w - x)}{2L\mu}
\]

where \(v(x)\) is the longitudinal velocity at the \(x\) coordinate, \(\Delta P\) is the pressure drop along the channel of length \(L\), and \(\mu\) is the viscosity of the carrier liquid. It holds for the average velocity (Equation 24):

\[
\langle v(x) \rangle = \frac{\Delta P w^2}{12L\mu}
\]

which is obtained by integration of Equation (23) over the whole thickness of the channel. An axially symmetric parabolic flow velocity profile is the most frequent case found in practice. However, it might be advantageous to construct a channel in which an axially asymmetrical flow velocity profile is formed. This interesting possibility is discussed in sections dealing with specific FFF methods and techniques.

### 2.4 Convolution of Transverse Concentration and Flow Nonuniformities

Separated species undergo two fundamental transport processes, transverse flow caused by the imposed field and longitudinal hydrodynamic flow. The separation is due to interference of the established concentration and flow nonhomogeneities. Whenever the exponential concentration distribution across the channel of each sample component is established under static conditions without hydrodynamic flow, the zones of all components are superimposed. Only under dynamic conditions, with the liquid flow applied, can separation of the individual zones occur. The sample components are transported in the direction of the longitudinal axis of the channel at different velocities, that depend on the distance of their centers of gravity from the channel accumulation wall. Larger species are usually compressed closer to the accumulation wall and, consequently, the elution order is from the smallest particles to the largest ones. Polarization FFF usually exploits constant driving forces; however, this can be varied during elution by programming.

Two limiting cases in polarization FFF are related to the intensity of the field forces. When this intensity is zero, the transverse flux of the separated species may occur under laminar flow conditions due to the shear forces. As a result, axial separation may occur as in hydrodynamic chromatography.\(^{14}\) If the driving forces are strong enough to concentrate all components as close as possible to the accumulation wall, the mean distance of Brownian motion is lower than any component radius and the mean distance of the species from the accumulation wall is equal to their radius. Consequently, larger species migrate into streamlines of higher velocities than smaller ones, and are eluted more rapidly. In principle, any effective field may be applied to this steric mode of FFF (Figure 4).\(^{8}\)

The situation is quite different for the convolution of Gaussian concentration distribution of the separated sample components appearing in focusing FFF with an axially symmetrical flow velocity profile. In this case, partial or complete separation can occur of the individual zones of some or all sample components in the \((x\) axis) direction of the field. The resolution already achieved by focusing should not be degraded by the additional hydrodynamic transport in the longitudinal direction. It is evident, that if some of the zones are focused at the same but opposite distances from the central longitudinal axis of the channel, they are transported by the flow at identical velocities. Therefore, no longitudinal separation occurs even when the focused zones are well separated in the direction of the focusing field action. A convenient solution is to exploit only one half of the channel or to establish the conditions under which the asymmetrical flow velocity profile is formed. In such a case, the combination of the axially asymmetrical

\[\text{Figure 4 Principle of steric FFF. All sample components are in contact with the accumulation wall as a result of the high intensity of the applied field. As a result, steric hindrance causes larger particles to be eluted more rapidly than the smaller ones.}\]
flow velocity profile with the Gaussian concentration distribution has the advantage that quasitotal volume of the channel can be used for the separation. It is demonstrated below that an important increase in the resolution of the focused zones can be achieved under dynamic conditions in comparison with the resolution obtained in the direction of the focusing processes under static conditions. This was an important finding, which demonstrated theoretically and experimentally the major advantage of dynamic focusing FFF over classical focusing separations performed under static conditions.\(^\text{(15)}\)

### 2.5 Retention

Retention relates the elution velocity of the sample component in question with the average velocity of the carrier liquid. The average velocity of the zone migration of a retained sample component in the direction along the channel is given by Equation (25),

\[
\bar{v}_{r,\text{ave}} = \frac{\langle c_\ast(x)v(x) \rangle}{\langle v(x) \rangle} \tag{25}
\]

where the angle brackets denote average values. The retention ratio \(R\) is defined as the average velocity of a retained sample component to the average velocity of the carrier liquid which is equal to the average velocity of an unretained sample component (Equation 26):

\[
R = \frac{\bar{v}_{r,\text{ave}}}{\langle v(x) \rangle} \tag{26}
\]

The integral form of Equation (26) is Equation (27):

\[
R = \frac{\int_0^w c(x)v(x) \, dx}{\int_0^w c(x) \, dx} \int_0^w v(x) \, dx \tag{27}
\]

where \(v(x)\), \(c(x)\) are the local velocity and concentration, respectively, of the retained species. Both vary as a function of the transverse position in the direction of the \(x\) axis. The calculation of the retention ratio \(R\) gives different relationships for various concentration distributions of the retained species, corresponding to either polarization or focusing mechanisms, and various symmetrical or asymmetrical flow velocity profiles. From the practical point of view, the retention ratio \(R\) can be expressed as the ratio of the experimental retention time \(t_0\) or the retention volume \(V_0\) of an unretained sample component to the retention time \(t_r\) or the retention volume \(V_r\) of the retained sample component (Equation 28).

\[
R = \frac{t_0}{t_r} = \frac{V_0}{V_r} \tag{28}
\]

The retention volume of the unretained sample component should be equal to the void volume of the fractionation channel. The deviations from this ideal case can be caused by flow imperfections inside the channel and by extrachannel elements of the separation system. However, they are usually negligible for a carefully built separation system.

FFF is often performed in channels of simple geometry, which assists in establishing a rigorous analytical relationship between the retention ratio and the position of the center of gravity of the concentration distribution in the direction of the \(x\) axis. As in many cases, a known relationship between the position of the center of gravity of the zone and the molecular parameters of the sample component exists, the size parameters can be calculated from the experimental retention data without the need for a calibration procedure.

### 2.6 Retention Ratio in Polarization Field-flow Fractionation

Substitution for \(c(x)\) and \(v(x)\) in Equation (27) and integration give Equation (29):

\[
R = 6\lambda \left( \coth \left( \frac{l}{2\lambda} \right) - 2\lambda \right) \tag{29}
\]

where \(\lambda = l/w\). This equation is the basic relationship for the retention in polarization FFF performed in an ideal channel composed of two parallel and infinite planes.\(^\text{(16)}\) If \(\lambda\) is small, \(\coth(1/2\lambda)\) approaches unity and the approximation of Equation (30) holds:

\[
\lim_{\lambda \to 0} R = 6(\lambda - 2\lambda^2) \tag{30}
\]

Thus, for very small \(\lambda\), Equation (31) is true:

\[
\lim_{\lambda \to 0} R = 6\lambda \tag{31}
\]

The graphical representations of Equations (29) to (31) are given in Figure 5. The retention ratio \(R\) can theoretically reach values from 1 (for an unretained sample component) to 0 (for a totally retained sample component). It can be seen that the above approximations are acceptable within the range of common experimental errors for \(R < 0.25\).

Equation (29) cannot be used to calculate \(\lambda\) directly from the experimental retention ratio. A numerical iteration procedure must be applied. Equation (30) represents a good first iteration step in a computer iteration procedure. The physical meaning of \(\lambda\) can be best understood by taking into account that the force of the friction counteracting the movement of the particle due to the applied field is proportional to the product of the
Figure 5 Dependence of the retention ratio $R$ on the retention parameter $\lambda$ calculated from rigorous and approximate relationships for polarization FFF.

velocity $U$ and of the friction coefficient $f$ (Equation 32):

$$f = \frac{R T}{D}$$

At the steady state, the force of the friction is equal to the force acting on a sample component due to the effective field. Equation (33) holds for the friction coefficient:

$$f = \frac{R T}{D}$$

where $R$ is the gas constant and $D$ is Avogadro’s number. Thus the velocity of the particle migration in the direction of the field action is determined by the ratio of the effective field force to the friction coefficient (Equation 34):

$$\lambda = \frac{k T}{F_w} \quad \text{or} \quad \lambda = \frac{R T}{F_w}$$

The parameter $\lambda$ is then the ratio of the thermal energy to the effect of the field on one particle. The above relationships enable evaluation of the size characteristics of the retained sample components from the experimental retention data. Whenever a straightforward relationship between the retention parameter $\lambda$ and the size of the retained sample component exists, the size can be directly calculated from experimentally determined $R$ values. Nevertheless, even in those cases when the relationship between $\lambda$ and the size of the separated sample component is not known, it can be established by a convenient calibration procedure.

Most channels used for polarization FFF are constructed with a rectangular cross-section having a large width to thickness ratio that approaches an ideal two-infinite-parallel-planes configuration. In a few cases, a cylindrical capillary tube has been used as an FFF channel, so that the circular symmetry with respect to the central longitudinal axis has to be taken into account. The two distinct situations that can occur under these conditions are shown in Figure 6. In the first case the field-induced transport of the separated particles is generated in the radial direction from the central longitudinal axis of the cylindrical channel to the wall. The resulting radial concentration distribution is circularly homogeneous. This situation occurs when, for example, a semipermeable wall allows a radial uniform flow of a liquid due to the pressure difference between the interior and exterior of the cylindrical capillary, but retains larger size particles. The second situation is with an external field applied across the circular cross-section capillary.

An axially asymmetric flow velocity profile can be formed in a cross-sectional permeability separation channel whose cross-section is not rectangular but, for example, trapezoidal. This type of channel can exhibit important advantages when used for focusing FFF.
FIELD-FLOW FRACTIONATION IN PARTICLE SIZE ANALYSIS

However, the convolution of an axially asymmetrical flow velocity profile with an exponential concentration distribution does not improve the separation. This is because the central part of the velocity profile is often quasiparabolic, which is not advantageous when compared to a parabolic symmetrical flow velocity profile.

2.7 Retention Ratio in Focusing Field-flow Fractionation

General retention theory for focusing FFF\(^\text{(16)}\) has been developed for basic shapes of fractionation channel cross-section, starting from the idea of sedimentation-flotation focusing field-flow fractionation (SFFFFF).\(^\text{(2)}\) As mentioned above, the use of an axially symmetrical (e.g., parabolic) flow velocity profile results in being unable to separate two focused zones with the same, but opposite, distances from the central axis of the channel. To avoid this problem, it is possible to use only one half of the channel between one wall and the central axis, or to divide the channel at the end by a longitudinal splitting to conduct each half of the carrier liquid via a separate output. However, it is then necessary to use two independent detectors and this might be an experimental difficulty for analytical applications. Another solution is to form an axially asymmetrical flow velocity profile in the plane of the focused zones. These possibilities represent a challenge for fundamental methodological research, and have not been developed to a level suitable for analytical applications. Consequently only the simplest relationship, describing retention in infinite parallel planes geometry or in rectangular cross-section channels, for which the ratio of the channel width to its thickness is large enough, is given here.

The retention ratio \( R \) can be calculated by substituting from Equations (22) and (23) into Equation (27) and by integration. The approximate solution for infinite parallel planes configuration or for rectangular cross-section channel is (Equation 37)

\[
R = 6(\Gamma_{\max} - \Gamma_{\text{max}}^2)
\]

where \( \Gamma_{\max} = \frac{x_{\max}}{w} \) is the dimensionless coordinate of the maximal concentration of the focused zone. Numerical calculations have confirmed that Equation (37) represents a good approximation of the exact solution\(^\text{(38)}\) provided that the focused zone is narrow. Relationships for retention in channels of other than rectangular cross-section can be found elsewhere.\(^\text{(15)}\)

2.8 Zone Dispersion

Any separation process is accompanied by zone broadening due to the spreading processes that have a tendency to disperse the concentration distribution already achieved by separation. The efficiency of the separation increases with decreasing proportion of these dispersive processes. A conventional parameter that describes quantitatively the efficiency of any separation system is the height equivalent to a theoretical plate \( H \) (Equation 38):

\[
H = L \left( \frac{\sigma}{V_t} \right)^2
\]

where \( V_t \) is the retention volume and \( \sigma \) is the standard deviation of the elution curve of a sample component. The width of the elution curve described by the standard deviation reflects several contributions to the zone broadening: longitudinal diffusion; nonequilibrium and relaxation processes; spreading due to the external parts of the whole separation system, such as the injector, detector, connecting capillaries, etc. A graphical representation of these contributions as a function of the average linear velocity of the carrier liquid is shown in Figure 7. The sum of all contributions results in a curve which exhibits a minimum. As the diffusion coefficients of the particles are very low, the longitudinal diffusion is practically negligible and the optimal efficiency (the minimum on the resulting curve) is at a very low flow velocity. Instrumental and relaxation spreading can be minimized by optimizing the experimental conditions. From the practical point of view, whenever the zone dispersion cannot be suppressed enough by optimization of the experimental conditions, then correction of the fractograms for zone broadening must be applied. These correction procedures are discussed below.
2.8.1 Relaxation

An important contribution to zone broadening is from relaxation processes, but it can be reduced by a convenient experimental procedure. The concentration distribution of the fractionated sample across the channel immediately after the injection is far from equilibrium; the steady state is established progressively. If the flow is stopped after injection for a time necessary for the relaxation, the shift of the retention volume and the zone spreading can be suppressed. It is even possible to continue the elution with a higher velocity after a stop-flow period without losing the efficiency and resolution. The effect of this relaxation on the height equivalent to a theoretical plate, and retention and its suppression by the stop-flow procedure, is demonstrated in Figure 8.19

If the intensity of the field varies during the elution (e.g. by programming), the additional, secondary relaxation processes occur. However, deviation from the steady state is minor if the variation of the field intensity is slow enough.

2.9 Particle Size Distributions

Most of real particulate samples are not uniform in size but exhibit a heterogeneity (polydispersity) that can be described by a distribution function. The PSD function, or simply the PSD, is a numerical or graphical representation of the relative proportion of each particle size composing the whole analyzed sample. A minimal particle size difference in a polydisperse sample is given by an increment which corresponds to a construction unit of the particles in question. The increment can be a molecule of a given size, the monomer unit if the particle is a polymer, or the aggregate of many molecules, etc. As a result, each PSD has a discrete character. This is demonstrated in Figure 9 where the PSD of a model sample is composed of six different diameters, \( d_1 \) to \( d_6 \). The heights \( h_i \) represent the corresponding amounts of the particles of the diameter \( d_i \) (e.g. \( h_2 \) for the particle of the diameter \( d_2 \)). This amount can be expressed as the number of particles of a given diameter relative to the number of all particles in the sample (Equation 39),

\[
N_i = \frac{n_i}{\sum_{0}^{\infty} n_i} \tag{39}
\]

or as the mass of the particles of a given diameter relative to the total mass of the sample (Equation 40),

\[
M_i = \frac{m_i}{\sum_{0}^{\infty} m_i} \tag{40}
\]

Accordingly, the PSDs are called number or mass PSDs. A separation method such as FFF provides the experimental data (a fractogram) that can be treated in order to obtain the required true PSD. The PSD can
be used further to calculate various average particle sizes, polydispersity indexes (e.g. the standard deviation), and higher statistical parameters of the distribution function which represent a quantitative numerical information about the shape (asymmetry, etc.) of the experimentally measured PSD.

The increment between two closest particle sizes is usually too small to be distinguished by any separation method. The resulting fractogram is therefore a superposition of the individual particle sizes, and the physically discrete PSD is approximated by a continuous distribution function as shown graphically in Figure 9. The approximation can be performed by using standard methods of nonlinear regression. The raw experimental PSDs are very often and successfully approximated either by a continuous Gaussian distribution function, as defined by Equations (41) and (42), or less frequently by a discrete distribution, such as a Poisson distribution as defined by Equations (43) and (44).

The unnormalized Gaussian (differential) mass distribution function is

\[
M(d_i) = \frac{\exp[-(d_i - d_{\text{max}})^2/2\sigma^2]}{(2\pi\sigma^2)^{1/2}}
\]

and the corresponding unnormalized Gaussian number distribution function is

\[
N(d_i) = \frac{6}{\pi d_i^3 \rho_i^{1/2}} \frac{\exp[-(d_i - d_{\text{max}})^2/2\sigma^2]}{(2\pi\sigma^2)^{1/2}}
\]

The unnormalized discrete Poisson (differential) number distribution function is

\[
N(P - 1) = \frac{\exp(-r)r^{P-1}}{(P - 1)!} \quad \text{with} \quad P = 1, 2, 3, \ldots
\]

which can be easily converted into mass distribution function

\[
M(P) = \frac{P \times N(P)}{\sum_0^\infty P \times N(P)}
\]

The PSD can take the form of a differential distribution or a cumulative (integral) distribution. If the detector response is proportional to the mass of the particles, the differential mass distribution function \(M(d_i)\) can be converted into integral mass distribution function \(I_m(d_i)\) by Equation (45):

\[
I_m(d_i) = \int_0^\infty M(d_i) \, dd_i
\]

Analogically, for integral number distribution function (Equation 46):

\[
I_n(d_i) = \int_0^\infty N(d_i) \, dd_i
\]
The number average particle diameter can be calculated from the same fractogram by using Equation (48), provided that the density $\rho_i$ is constant and independent of the particle diameter:

$$\bar{d}_n = \frac{\sum_0^\infty n_i d_i}{\sum_0^\infty n_i} = \frac{\sum_0^\infty h_i}{\sum_0^\infty h_i/d_i}$$

(48)

because Equation (49) holds true:

$$n_i = \frac{h_i}{m_i} = \frac{6h_i}{\pi \rho_i d_i^3}$$

(49)

The polydispersity (the width of the distribution curve) can be conveniently and most simply characterized by the index of polydispersity (Equation 50):

$$I = \frac{\bar{d}_m}{\bar{d}_n}$$

(50)

Another possibility is to calculate the standard deviation $\sigma$ of the PSD from the fractogram, defined by Equation (51):

$$\sigma = \frac{1}{\sum_0^\infty h_i} \left( \sum_0^\infty (d_i - \bar{d}_n)^2 h_i \right)^{1/2}$$

(51)

A graphical representation of the meaning of standard deviation of a model fractogram is given in Figure 12.

All above-mentioned PSD characteristics are derived from the defined statistical moments $\mu$ and central statistical moments relative to zero $\mu_0$ of the $j$th order of a general distribution function $F(x)$ (Equations 52 and 53):

$$\mu_j = \frac{\int_{-\infty}^{+\infty} x^j F(x) \, dx}{\int_{-\infty}^{+\infty} F(x) \, dx}$$

(52)

$$\mu_{0,j} = \frac{\int_{-\infty}^{+\infty} (x - \mu_1)^j F(x) \, dx}{\int_{-\infty}^{+\infty} F(x) \, dx}$$

(53)

where Equation (54) must be satisfied for the normalized moments:

$$\int_{-\infty}^{+\infty} F(x) \, dx = 1$$

(54)

2.9.2 Correction of Particle Size Distribution for Zone Broadening

Section 2.8 demonstrated that a zone corresponding to a separation of a uniform particulate species is broadened due to dispersive processes. Consequently, the resulting fractogram of a polydisperse sample is a superposition of two processes: separation of discrete size particles and zone broadening. This is shown in Figure 13 where five different particle size fractions elute at different elution volumes, in which their zones are spread and overlapped, and the resulting fractogram is a convolution of all individual zones. The apparent PSD, calculated directly from such a raw experimental fractogram by using the above relationships, is broader than the true one.

To obtain an accurate PSD, corresponding average particle sizes, and polydispersity indexes, a correction procedure for the zone broadening should be used. An efficient correction method, applicable to FFF, was described by Jánhonová et al. This method was derived from more general correction procedures, currently used.

Figure 12 Graphical evaluation of the standard deviation $\sigma$ from a fractogram. The distance between the sections of the tangents at inflection points with the baseline determines $4\sigma$.

Figure 13 The fractogram of a sample of discrete PSDs is a superposition of the spread of zones of the individual discrete size species.
in size exclusion chromatography of polymers.\textsuperscript{(21)} It is based on the above idea that a real experimental fractogram \( h(V) \) of a polydisperse particulate sample is a convolution of two distribution functions, namely the fractogram corrected for zone broadening and which corresponds to the true PSD \( g(Y) \), and the spreading function \( G(V,Y) \) that represents the normalized detector response to a uniform particulate fraction having the elution volume \( Y \) (Equation 55):

\[
h(V) = \int_0^\infty g(Y)G(V,Y)\,dY \quad (55)
\]

where \( V \) and \( Y \) are then the elution volumes. Equation (55), called Tung integral equation, is the basis for all well-known correction methods.\textsuperscript{(21)} It can be solved analytically only under certain conditions. It is, above all, the requirement of a uniform spreading function. In such a case, it becomes a convolution integral (Equation 56):

\[
h(V) = \int_0^\infty g(Y)G(V-Y)\,dY \quad (56)
\]

In a number of practical cases, the spreading function can be approximated by the normal Gaussian function (Equation 57):

\[
G = \frac{1}{2\pi\sigma_s^2} \frac{1}{2\sigma_v^2} \exp\left(-\frac{(V-Y)^2}{2\sigma_v^2}\right) \quad (57)
\]

where \( \sigma_s \) is the standard deviation of the spreading function which is assumed to be independent of the elution volume. As this independence is valid in FFF only for a restricted range of elution volumes, Equation (57) can only be applied to fractograms of samples with a narrow PSD. However, if a nonuniform spreading function is used, the correction procedure can be applied to samples exhibiting wider PSDs (Equation 58):

\[
h(V) = \int_0^\infty \left(g(Y)\frac{1}{2\pi\sigma_s^2(Y)}\right)^{1/2} \exp\left(-\frac{(V-Y)^2}{2\sigma_v^2(Y)}\right)\,dY \quad (58)
\]

This function can be numerically solved. A graphical representation of a model result of the application of correction procedure is shown in Figure 14.

A practical application of the above-described treatment of an experimental fractogram is demonstrated by the real fractogram of a polymer latex obtained from sedimentation FFF, reproduced in Figure 15. The flowchart of the correction program is shown in Figure 16, and the resulting corrected PSD is compared with the uncorrected one in Figure 17.

Some authors have confirmed and extended the treatment of raw FFF experimental fractograms in order to correct the PSD for zone broadening.\textsuperscript{(22–24)}

![Figure 14](image-url) Effect of applying a zone-spreading correction to an uncorrected fractogram.

![Figure 15](image-url) Treatment of an experimental sedimentation FFF fractogram of a polymer latex.

2.9.3 Practical Data Treatment

In following sections, the dependences of the retention ratio \( R \) on the diameter of the fractionated particles are discussed for various polarization FFF methods. If such a dependence is not linear but the segmentation of the experimental fractogram is regular (i.e. that \( \Delta V_i \) between the \( h_i \) values is constant), the increment of the particle diameter \( \Delta d_i \) varies with corresponding \( h_i \) values. This fact must be taken into account in the experimental data treatment in order to obtain the accurate results.\textsuperscript{(25)} The equations that follow give accurate relationships concerning various transformations of the integral to differential distributions and vice versa, and conversions of the raw experimental fractograms into PSDs. The differential mass PSD can be calculated by differentiating the integral PSD (or cumulative fractogram) according to Equation (59):

\[
M(d_p) = -\frac{dI(d_p)}{dd_p} = -\frac{dI(V)}{dV} \frac{dV}{dV(d_p)} \frac{dV(d_p)}{dd_p} \quad (59)
\]
The cumulative particle mass values are calculated from Equation (60),

\[ I(V) = \frac{1}{A_T} \sum_i A_i(V_i) \quad (60) \]

where \( A_T \) is the total area of the fractogram. If needed, the differential number PSD can be deduced from mass PSD by Equation (61):

\[ N(d_p) = \frac{M(d_p)}{d_p} = \frac{h_i}{\sum_i h_i} \frac{\Delta V_i}{\Delta d_p} \quad (61) \]

If \( M(d_p) \) and \( F(V) \) are, respectively, the mass PSD and the experimental fractogram, the total mass of particles can be expressed by Equation (62):

\[ \sum_i M'(d_p) \Delta d_i = \sum_i F'(V) \Delta V_i \quad (62) \]

and, by considering the relationship between the retention volume and the particle size, \( V = g(d_p) \), and its derivative \( g'(d_p) \) (Equation 63),

\[ g'(d_p) = \frac{\Delta V_i}{\Delta d_i} \quad (63) \]

Equation (62) becomes Equation (64):

\[ \sum_i M'(d_p) \frac{\Delta d_i}{g'(d_p)} \Delta V_i = \sum_i F'(V) \Delta V_i \quad (64) \]

and, consequently (Equation 65),

\[ F'(V) = \frac{M'(d_p)}{g'(d_p)} \quad (65) \]

For example, Equation (47) can be expressed as Equation (66):

\[ \bar{d}_m = \frac{\sum_i d_i M'(d_p) \Delta d_i}{\sum_i M'(d_p) \Delta d_i} = \frac{\sum_i d_i F'(V) \Delta V_i}{\sum_i F'(V) \Delta V_i} \quad \text{etc.} \quad (66) \]
The acquisition of the experimental data and treatment of the fractogram are usually performed by a computer connected on line to the separation system.

3 METHODS, TECHNIQUES AND THEIR APPLICATIONS

The retention parameters $R$ or $\lambda$ are directly related to the effective diameters of the separated particles for some of the polarization techniques, such as sedimentation FFF. This relationship is not straightforward for some other polarization FFF methods. For example, $\lambda$ is a complex function of the size and charge for electric FFF. It is a function of the thermal diffusion factor, which is a function of the diffusion coefficient and of the coefficient of the thermal diffusion, and the diffusion coefficient is inversely proportional to the size of the fractionated species, but a definite form of this dependence does not exist in thermal FFF.

The transverse positions of the zones and, as a result, the values of $\Gamma_{\text{max}}$ in focusing FFF are related to the corresponding extensive properties of the fractionated samples, such as the density. The intensive properties often influence the width of the focused zones.

FFF is then used to characterize and to analyze quantitatively the properties related to the retention. Even if the determined characteristic of the separated sample is not explicitly related to the retention parameter, an empirical calibration can be established by first using known standards which are subsequently applied thereafter to determine this characteristic of the sample under investigation.

3.1 Polarization Field-flow Fractionation

The character of the applied field determines the particular method of polarization FFF. The most important of them, which have already found many practical applications in particle size analysis, are sedimentation FFF, flow FFF, electric FFF, and thermal FFF.

Other techniques have been proposed but their routine laboratory practice remains to be elaborated.

3.1.1 Sedimentation Field-flow Fractionation

This technique is based on the action of gravitational or centrifugal forces on the suspended particles. The sedimentation velocity is proportional to the product of the effective volume and density difference between the suspended particles and the carrier liquid. The channel is placed inside a centrifuge rotor, as shown in Figure 18. The technique can be applied to the analysis and characterization of polymer latex particles, inorganic particles, emulsions, biological cells, etc. The retention parameter $\lambda$ depends on the effective mass of the particles according to Equation (67):

$$\lambda = \frac{6kT}{\pi d^3 g \Delta \rho}$$

where $g$ is the gravitation or centrifugal acceleration and $\Delta \rho$ is the density difference between the particles and the carrier liquid. Calculation of the PSD is possible directly from the retention data by applying Equation (67) without any calibration.

The fractionation and analysis of colloidal particles in river water, the analysis of diesel exhaust soot, and of nuclear energy-related materials, are typical examples of the use of sedimentation FFF in the investigation of environmental samples. Oil emulsions and particles of biological origin are among the most interesting objects to have been fractionated. The performance of sedimentation FFF is superior to or as good as other separation methods. A complication in interpreting experimental data is that the retention is proportional to the product of particle size and particle density. When performing fractionation in a single carrier liquid, the density must be assumed constant for all particles. However, it is possible to determine the size and density of the particles independently if fractionations are performed in more carrier liquids of various densities.

A typical application of sedimentation FFF which allowed detection of a bimodal PSD in a sample of a polymer latex (supposed originally to have a very narrow and monomodal PSD) is shown in Figure 19(a). The order of the elution from the small to the large diameter particles corresponds to the polarization mechanism. Figure 19(b) shows a rapid, high resolution sedimentation FFF of the polymer latex particles. The separation was carried out at high centrifugal force; the mechanism of steric FFF dominated, and the order of the elution was inverted.
action of both mechanisms can be displaced to avoid the deterioration of the separation.

Refinements to sedimentation FFF have generated new applications of this technique to the PSD analysis of samples of very diverse origin.\(^{30-42}\)

### 3.1.2 Flow Field-flow Fractionation

Flow FFF is a universal method because the cross-flow, perpendicular to the flow of the carrier liquid along the channel, creates an external hydrodynamic field that acts on all particles uniformly,\(^{43,44}\) and separation of particles of different sizes is caused by the differences in diffusion coefficients. The channel (Figure 21) is formed between two parallel semipermeable membranes fixed on porous supports, which maintain the uniform distribution of the cross-flow over the whole surface. The carrier liquid can permeate through the semipermeable membranes but the separated particles cannot. The retention parameter \(\lambda\) is given by Equation (68):

\[
\lambda = \frac{kTV_0}{3\pi\mu V_C w^2 d_p}
\]

where \(V_0\) is the void volume of the channel, \(\mu\) is the viscosity of the carrier liquid, and \(V_C\) is the volumetric velocity of the cross-flow. Flow FFF can also be carried out in a circular cross-section capillary. Radial forces are due to an internal over-pressure\(^{45}\) which causes flow of the carrier liquid through the semipermeable cylindrical capillary. The advantage of this arrangement is lower dilution of the separated particles during elution, which is caused by a partial depletion of the liquid due to the radial cross-flow.

One example of an interesting application of flow FFF is shown in Figure 22: the retentions of two silica samples injected separately and in a mixture\(^{46}\) indicated that the separation was not influenced by interactions between two particulate samples. The availability of the membranes and semipermeable capillaries compatible

Figure 20 Dependence of the retention ratio on particle size for polarization and steric mode FFF at two different centrifugal forces. The dotted curve is for the lower force.

The domains of two competitive mechanisms are shown in Figure 20. The retention ratio decreases with increasing particle size in the range of the polarization mechanism and increases when the steric FFF mechanism prevails. When both mechanisms are in competition, the particles of different sizes can elute unseparated. However, if the field force is modified, the domain of the simultaneous

FIELD-FLOW FRACTIONATION IN PARTICLE SIZE ANALYSIS

Figure 22 Flow FFF fractograms of two different samples of colloidal silica obtained separately (peaks 1 and 2) and in a mixture (peak 3).

with various solvents allows the operation of flow FFF with both water-based and organic solvents.

The original construction of the flow FFF channel was proposed and implemented experimentally. Only the accumulation wall of the channel is semipermeable, so that a part of the carrier liquid passes through the membrane thus generating the hydrodynamic flow field across the channel. In order to optimize the linear velocity of the longitudinal flow, the channel width decreases from the inlet to the outlet. However, the hollow fiber capillary used as a fractionation channel was found to be a simple and convenient solution for flow FFF.

Some selected review articles demonstrate a large field of practical applications of flow FFF in PSD analysis.

3.1.3 Electric Field-flow Fractionation

Electric FFF uses an electric potential drop across the channel to generate a transverse flux of charged particles. The walls of the channel are usually formed by semipermeable membranes that allow the passage of the small ions but not the permeation of the separated particles (Figure 23). The dependence of the retention parameter \( \lambda \) on the electrophoretic mobility \( \mu_e \), and the diffusion coefficient of the charged particles is given by Equation (69):

\[
\lambda = \frac{D}{\mu_e E w}
\]

where \( E \) is the electric field strength. The ratio of the diffusion coefficient to the electrophoretic mobility of the particles determines the retention in electric FFF. The particles exhibiting only small differences in electrophoretic mobilities but with an appreciably broad PSD and, consequently, important differences in diffusion coefficients, can be separated. The advantage of electric FFF compared with electrophoretic separations such as capillary electrophoresis, is that high electric field strength can be achieved at low absolute values of the electric potential due to a small distance between the walls of the channel.

Electric FFF is especially suited to separations of biological cells as well as charged polymer latexes and other colloidal particles. The separation is strongly influenced by the concentration of the injected sample, the concentration of the buffer solution, the pH, and by interparticle interactions. This can produce experimental difficulties for conventional fractionations; however, it can be exploited for investigation into the interactions of charged particles. As for flow FFF, electric FFF can be carried out by using a semipermeable tube of circular cross-section with the electric field applied transversally. Fractionation of charged particles represents a wide field of application.

3.1.4 Thermal Field-flow Fractionation

Thermal FFF was the first experimentally implemented technique. Until recently it was used mostly for the fractionation of macromolecules; now there have been some attempts to apply this method to the fractionation of particles. The future potential of thermal FFF justifies a brief description of this technique, regardless of its recent limited use for the PSD analysis.

The temperature difference between two metallic bars, forming the channel walls with highly polished surfaces and separated by a spacer in which the channel proper is cut, produces the flux of the sample components, known as Soret effect, usually toward the cold wall. The construction of a channel for thermal FFF is shown in Figure 24.
The relation between the characteristic of the fractionated particles, and the operational variables is given by Equation (70):

$$\lambda = \frac{D}{wD_T(dT/dx)}$$  \hspace{1cm} (70)

where $D_T$ is the coefficient of the thermal diffusion which depends on the chemical composition and structure of the fractionated species but not on their size. As a result, the differences in thermal diffusion coefficients allow fractionation according to differences in chemical composition and structure. However, the diffusion coefficient $D$ depends on the size which should allow fractionation according to PSD.

Although it might appear possible to evaluate molar masses or particle sizes from an experimental fractogram by using simply Equation (70), an empirical calibration curve (Figure 25\(^{66}\)) is usually constructed by using a series of samples of known characteristics. The experimental retention ratios are used to plot the calibration curve. This calibration can be used to determine the characteristics of an unknown sample of the same chemical composition and structure with the same temperature gradient applied.

The most frequent applications of thermal FFF concern polymers. The pressurized separation systems permit operation above the normal boiling point of the solvent used. The fractionations can be finished in a few minutes or seconds. Performance parameters favor thermal FFF over the competitive methods, at least for the fractionation of macromolecules. The fractogram in Figure 26(a) shows a wide range of the polymer molar masses which can be determined in a single experiment by using time-programmed temperature gradient.\(^{67}\) Figure 26(b) demonstrates ultrarapid and high-resolution thermal FFF.\(^{68}\)

As concerns the fractionation of the particles and consecutive analysis of the PSD, the actual potentials of thermal FFF have to be verified experimentally and theoretically. It has been shown that various particles exhibit retention in thermal FFF.\(^{69,70}\) However, the retention phenomenon is driven by surface properties of the retained particles\(^{71–75}\) and, consequently, the characterization of PSD of a studied sample from thermal FFF data is not yet easy.

3.1.5 Other Polarization Field-flow Fractionation Methods

Other polarization FFF methods include magnetic FFF, concentration FFF (making use of a concentration gradient of a mixed solvent to induce the chemical potential gradient), and shear FFF. Although these methods may become highly relevant for PSD analysis in the near future, their recent technical level does not allow their routine use.

Each of the above-described polarization FFF methods can apply the field, of constant or variable strength, during the fractionation. Steric FFF is applicable independently of the physical character of the field, but gravitation or centrifugal forces or the cross-flow of the carrier liquid are the most frequently used for the fractionation of practically important particles such as the coal particles.
human and animal cells, particles originating from the environment, etc. Precautions must be taken to prevent problematic situations that can occur when some particles may undergo steric exclusion, with the elution order from large to small, while other particles can experience polarization, with the elution order inverted.

### 3.2 Focusing Field-flow Fractionation

Focusing FFF is less developed than polarization FFF and, consequently, has not yet been exploited in routine laboratory work due to its substantially shorter history. Focusing FFF methods can be classified according to various combinations of the driving field forces and gradients:

- effective property gradient (perichoric gradient) of the carrier liquid;
- preformed perichoric gradient;
- cross-flow velocity gradient;
- lift forces;
- shear stress;
- gradient of nonhomogeneous field action.

These principles are promising for PSD analysis and merit brief discussion here.

#### 3.2.1 Perichoric Gradient of the Carrier Liquid Combined with a Field

Focusing can occur due to the effective property gradient of the carrier liquid in the direction across the channel, combined with a primary or secondary transverse field. The density gradient as in SFFFFF or the pH gradient as in isoelectric focusing field-flow fractionation (IEFFFF) have already been implemented.\(^{9,10,12,13,76,77}\) Two simple channels are demonstrated in Figures 27(a) and 28(a) as well as two examples of practical applications showing the separation of two types of the polystyrene latex particles by SFFFFF (Figure 27b) and the separation of two components of horse myoglobin by IEFFFF (Figure 28b).

The separation by SFFFFF was carried out according to the density difference of the latex particles, whereas the electric field was applied to generate the density gradient in a suspension of charged silica particles. The separation by IEFFFF was carried out according to the isoelectric point differences by using the electric field to generate the pH gradient and to focus the sample components.

Retention theory for the special case of focusing FFF in a density gradient is developed here in more detail because a similar approach can be applied to all the methods and techniques described below. The transverse gradient can be generated, for example, in a binary or multicomponent carrier liquid whose two or more components are affected unevenly by the primary homogeneous field. The primary field can also act to form the focused zones of the separated sample components. Another possibility is to superimpose a secondary field of different nature on the gradient generated by the primary field.\(^{9,10,12,13}\) The density gradient can be generated by centrifugal or electric field forces acting on colloidal particles, suspended in a liquid. The concentration distribution of the perichoric modifier particles due to the primary field is described by identical exponential distribution function as in the case of polarization mechanism (Equation 71):

\[
c_m(x) = c_m(0) \exp \left( -\frac{x|U|}{D_m} \right) \quad (71)
\]
Substituting into Equation (71) gives Equation (73):

\[ c_i = \frac{c(x)}{w} \frac{D_m}{U_m} \int_0^x \left( 1 - \exp \left( \frac{-wU_m}{D_m} \right) \right) \, dx \]

The concentration of the focused sample component, \( c_i \), can be calculated from the relationship for the average concentration (Equation 72):

\[ c_{m,ave} = \frac{w \int_0^x c(x) \, dx}{w} = c_m(0) \frac{D_m}{wU_m} \left( 1 - \exp \left( \frac{-wU_m}{D_m} \right) \right) \] (72)

Substituting into Equation (71) gives Equation (73):

\[ c_m(x) = \frac{c_{m,ave}wU_m}{D_m(1 - \exp(-wU_m/D_m))} \exp \left( \frac{-xU_m}{D_m} \right) \] (73)

The focusing force proper can be generated by combining the transverse gradient and the primary or secondary field action. Primary electric field can be applied to generate the density gradient due to the migration of the charged colloidal particles. The secondary gravitation coupled simultaneously with the established density gradient causes the focusing of a particulate sample component.

A modified version of Equation (20) for the focusing force gradient can be used to describe the focusing effect under these specific conditions (Equation 74):

\[ \frac{dc_i}{c_i} = -\frac{U_i(x)}{D} \, dx \] (74)

where \( c_i \) is the concentration of the focused sample component. The subscript \( i \) is used to distinguish between the concentration distribution, \( c_i(x) \), and the related parameters of the \( i \)th focused sample component and the concentration distribution, \( c_m(x) \), and the related parameters of the gradient forming component of the carrier liquid. Equation (73) can be transformed into density terms instead of concentrations (Equation 75):

\[ \rho(x) = \rho_i + \frac{\phi_{m,ave} \Delta \rho_{m,w} U_{m,e}}{D_m(1 - \exp(-wU_{m,e}/D_m))} \exp \left( \frac{-xU_{m,e}}{D_m} \right) \] (75)

The macroscopic focusing force acting on a single focused species can be calculated from Equation (76):

\[ F_i(x) = (\rho(x) - \rho_1) v_i g_f \] (76)

The concentration distribution of the focused particles in a density gradient formed simultaneously due to the action of primary electric field on two component colloidal carrier liquid is obtained by substituting into Equation (74) and by integration (Equation 77):

\[ c_i(x) = c_{i,\text{max}} \exp \left\{ -\frac{v_i g_f \phi_{m,ave} \Delta \rho_{m,w}}{kT(1 - \exp(-wU_{m,e}/D_m))} \right\} \times \left( \exp \left( -\frac{xU_{m,e}}{D_m} \right) - \exp \left( -\frac{x_{\text{max}} U_{m,e}}{D_m} \right) \right) \times \left( 1 + \frac{U_{m,e}(x_{\text{max}} - x)}{D_m} \right) \] (77)

where \( v_i \) is the volume of the focused particle, \( g_f \) is the acceleration of the focusing field, \( \phi_{m,ave} \) is the average volume fraction of the modifier, \( \Delta \rho_m = \rho_m - \rho_1 \) is the density difference between the modifier component and the suspending liquid and \( U_{m,e} \) is the velocity of the modifier species due to the primary electric field. Equation (77) was obtained without assuming the constancy of the density gradient. The Gaussian distribution, Equation (22), deviates substantially from Equation (77).\(^{9,10,12,13}\)
3.2.2 Preformed Gradient Combined with a Field
The effective property gradient of the carrier liquid, such as the density gradient, can be preformed at the beginning of the channel and combined with the primary or secondary field forces. The step density gradient is formed in such a case. The preforming is not limited to density gradient. A scheme of an experimental arrangement for this method and a typical experimental result\(^{78,79}\) is shown in Figure 29.

3.2.3 Cross-flow Velocity Gradient Combined with a Field
The focusing occurs in the transverse flow velocity gradient of the carrier liquid which opposes the action of the field. The longitudinal flow of the liquid is imposed simultaneously. This elutriation focusing field-flow fractionation (EFFFF) method has been investigated experimentally by using the trapezoidal cross-section channel\(^{80,81}\) but use of the rectangular cross-section channel is possible. The principle of the method and the result of fractionation of micrometer-size polystyrene latex particles are demonstrated in Figure 30.

3.2.4 Lift Forces Combined with a Field
The hydrodynamic lift forces that occur at high flow rates of the carrier liquid combined with the primary field, are able to concentrate the suspended particles into the focused layers.\(^{82}\) The retention of the particles under the simultaneous effect of the primary field and lift forces generated by the high longitudinal flow rate can vary with the nature of various applied primary field forces.

3.2.5 Shear Stress Combined with a Field
A high shear gradient in a carrier liquid can lead to the deformation of soft particles. The established entropy gradient generates the driving forces that displace the particles into a low shear zone.\(^{83}\) At a position where all the driving forces are balanced, the focusing of the sample components can occur.\(^{84}\) Although this method was originally proposed for a temperature gradient acting as a primary field, generating the thermal diffusion flux of the macromolecules which opposes the flux due to the entropy changes generated motion, in principle it should be applicable to soft particles as well.

3.2.6 Gradient of a Nonhomogeneous Field
A nonhomogeneous high-gradient magnetic field can be used to separate various paramagnetic and diamagnetic particles of biological origin by a mechanism of focusing FFF.\(^{85}\) A concentration of paramagnetic particles near the center of the cylindrical capillary and the focusing

of diamagnetic particles in a free volume of the capillary should occur. To our knowledge, no experimental results have yet been published.

3.2.7 Other Possibilities

Other gradients and a variety of fields can probably be combined to produce focusing, making these phenomena suitable for PSD analysis. The above discussions on the mechanisms exploited in focusing FFF give an idea as to their potential. More information on the state of the art can be found in a review. (86)

4 CONCLUDING REMARKS

Scientific progress passes through discoveries, inventions, and innovations. As a specific scientific discipline, analytical chemistry follows this process but also in the context of the whole area of scientific research. The polarization and focusing FFF methodologies represent an important contribution to the science and technology of separation, and the analysis of particles of synthetic or natural origin over a wide range of sizes, and of organized structures such as cells and microorganisms. Research and technology related to the life sciences and to macromolecular chemistry and technology, the analytical problems appearing in context with the protection of the environment, and many other scientific and technological activities, have stimulated the development of new analytical separation methods. The article shows that important contributions to experimental implementations have been obtained with model systems. The availability of commercial instrumentation systems is a crucial factor with regard to the progressive introduction of FFF methodologies into current laboratory practice. Moreover, it is important to recognise that all components of the apparatus are absolutely identical to those for liquid chromatography, with one exception – the separation channel. A liquid chromatograph can be modular, being composed of individual commercially available parts, such as the pump, injector, detector, etc., with a column that can be changed for individual applications. The FFF apparatus can be assembled similarly, with various channels which, in most cases, are easy to construct.

PARTICLE SIZE ANALYSIS

Filtration is defined as the separation of solid particles from a liquid or gas by passing the suspension through a porous, fibrous or granular substance. In science and industry, filtration is commonly used for the concentrating and/or removal of particulate matter or for the separation of particles into size classes for subsequent physical, chemical or biological analysis. Separation of particles into multiple size classes is often required for the assessment of particle size. There are many different types of filters available (e.g. fibrous, membrane, polycarbonate) for particle characterization through filtration. The type of filter to be used for particle size characterization is dependent on a number of considerations such as sample (particle) characteristics, collection efficiency, pore size and structure and analytical compatibility. Filtration has the advantage of being one of the few techniques which allow for the physical separation of particles into different size classes for distribution or chemical–biological analysis. If appropriate precautions are taken to minimize sample perturbations (e.g. select appropriate filter for the application, filter in the field, avoid overloading a filter, ensure a low flow rate and stir if possible), a reasonably accurate estimate of particle size can be obtained. Generally, errors associated with filtration arise from filter clogging and when attempting to characterize flocculated/aggregated particles. The basic nature of a suspended aggregate (i.e. fragile, plastic, high water content) means that it is likely to be broken up or created owing to the often tortuous nature of filtration, or be deformed on the surface or within the filter owing to pressure effects. This has implications if optical image analysis of the filter is to be used for particle size analysis as the true particle morphology and size will have been altered. In such an instance, if only a grain size distribution is required, it is suggested that optical image analysis be employed in conjunction with a plankton chamber settling technique rather than with filtration.

1 INTRODUCTION

Particles, and their interactions with their surrounding environments, have both theoretical and practical relevance within science and industry. Physical, chemical and biological processes are at play with or within particles and as such are known to play an important role in the biological and chemical dynamics of any aquatic and terrestrial environment and within engineered systems such as wastewater treatment. The definition of a “particle” in science is wide and varied depending on the discipline, and may incorporate a wide range of sizes, compositions and structures. Particles are considered to be dynamic and, in most cases, unstable relative to their surrounding environment, resulting in the majority of cohesive particles (<63 µm) existing primarily as flocculated or aggregated particles with a high propensity to assimilate and transport various nutrients and contaminants. As such, an accurate determination of particulate characteristics is of vital importance when dealing with issues of sediment and contaminant interactions. Common physical measurements of particle characteristics important to industry and the environment include grain size, surface area, specific gravity, surface charge, bulk density, shear stress, porosity and permeability. Grain size is the most significant of these characteristics in terms of a particle’s capacity to concentrate and retain contaminants owing to its controlling influence over many of the above characteristics. Hence, if only one physical characteristic of a particulate matter is to be determined for

PARTICLE SIZE ANALYSIS

industrial or environmental purposes as related to contaminants, grain size is by far the characteristic of choice.

Investigations into the chemically active fraction (<63 µm\(^2\)), the effects of particle size on the adsorption of contaminants\(^{11,13,14}\) and the association of microbes with particles,\(^{15}\) among others, often require that (a) the sediment be separated into a number of size fractions for subsequent analysis and/or (b) an accurate grain size distribution be obtained of the original sample. Such information and the associated chemical and/or biological analyses are often driven by environmental concerns, process control and monitoring demands and the development of new materials requiring evaluation. Accurate monitoring of particulate matter requires a knowledge of particle size distributions to assess fully health hazards, environmental conditions and industrial process efficiencies/deficiencies or performance. Particle fractionation and distributions are often used within models for sediment and contaminant source, fate and effect predictions in support of, or development of, environmental policies and management of water resources including wastewater treatment.

While there are a number of reviews of direct and indirect techniques for the fractionation of particulate matter into grain size ranges or for the determination of a particle size distribution,\(^{4,16–20}\) there is no standard technique, and as such, each method can produce significantly different results (this is particularly true when dealing with particles in aggregate form, as the majority of methods do not maintain the integrity of the particles). Grain size analysis is therefore an operationally defined property.

Direct optical image analysis with plankton chambers or filters provides the least destructive (to aggregates), most accurate, direct method of determining grain size distributions. However, if particle separation is required there are four other categories of techniques which allow for the separation of particles into size classes with a minimum of particle perturbation:\(^{20}\)

1. sieving, filtration, ultrafiltration and dialysis
2. sedimentation and centrifugation
3. field flow fractionation
4. hydrodynamic chromatography.

To date, categories 1 and 2 have been the most widely used methods for particle fractionation. Within these two categories, filtration, in spite of its drawbacks, is probably the most widely used, as its operational size range spans from the colloidal fraction up to and past what is considered the chemically active fraction (Figure 1). In addition, the chemical conditions in solution can be well controlled and particle size separation is generally well defined given appropriate controls. The primary chemical drawbacks are (a) possible contamination by metals and organic matter from the filter materials, (b) adsorption of “dissolved” compounds at the filter surface and (c) reactions induced by the filter, such as

aggregation of adsorbed natural organic material and adsorption of inorganic ions by particles retained on or within the filter. An understanding of the chemical interaction between particles, solute and filters is an important analytical requirement for any chemical or biological focused study. This relationship is beyond the scope of this article and only the physical aspects will be addressed. The primary physical drawbacks are related to the particle (aggregate) morphological changes and filter clogging resulting in a poorly defined size threshold. While sieving can be used for the fractionation of larger particles (most often used in the soil sciences) and ultrafiltration can be used for the fractionation of colloidal particles (although with great cost and time consumption), this article will focus primarily on the use of pressure or vacuum filtration in particle sizing and the appropriate size ranges associated with this method (Figure 1). In addition, the use of filters or plankton chambers with image analysis will also be discussed as a viable way of obtaining a grain size distribution. Although filtration is widely used for the filtration of aerosols from gases, this article will focus specifically on the sizing of particles from natural or engineered aqueous suspensions.

2 DEFINITIONS

2.1 Particle

It is universally accepted, and fundamental to science, that all matter is composed of particles. Figure 2 provides a breakdown of what is in environmental science generally is considered a particle. As with most definitions within science, however, the definition of a “particle” is operationally defined. Its definition in terms of composition, size range and structure is dependent on the objectives of the investigation, the process and environment under study and the operational restriction around the available tools or techniques for analysis. While there is no standard definition of a particle, the general standard size cutoff as to what would be considered a particle versus the dissolved phase is arbitrarily set at 0.45 µm. The difficulty in providing a standard definition of a particle is further complicated by the knowledge that particles rarely exist in a homogeneous state, with the exception of larger particles such as quartz (even this is debatable depending on the scale of observation, as such particles are likely to have bacterial, organic or ionic associations or coating of some sort) or smaller organisms such as bacteria (these too can often be incorporated within aggregated particles). These aggregates and flocs generally consist of an interrelated network of organic and inorganic particles resulting in complex physical, chemical and biological interactions not only within themselves but also with the medium in which they exist as a whole. These complex interactions, which will affect aggregate or floc function and structure, are illustrated in the conceptual model of floc form and function provided in Figure 3. A common problem within analytical chemistry is that all too often particle evaluations are performed on the constituent or absolute particles of the aggregates and not on the aggregates themselves. Such disregard for the integrity of the true particle structure and distribution can lead to erroneous results in evaluation or implementation of such important issues as environmental management/policy, health risk assessment and industrial performance.

Given that environmental analytical chemistry will focus mostly on the chemically active fraction (<63 µm), and that this fraction exists extensively as composite particles, this article will focus only on the sizing and fractionation of individual particles and flocculated or aggregated particles and their constituent particles down to a size of 0.45 µm. Therefore, for the purposes of this article, the term “particle” will be limited by structure and size and be defined as follows:

any physical entity or combination (aggregate/floc) of entities (inorganic or organic, viable or non-viable) within the solid phase having a minimum diameter within the range of 0.45 µm to the aggregate/floc size that a given environment will support (to a maximum 1000 µm).

This article will focus mostly on particles immersed or suspended within natural waters or within hydrous-engineered media and will not include soil-type aggregates or aerosols. The colloidal fraction will not be addressed here because of the extremely different physicochemical characteristics of these particles. A complete discussion on colloidal characterization can be found in Leppard and Buffie. The size range stated above is that which can be easily viewed by standard optical microscopy. For the purposes of this article, a floc is defined as a particle which has resulted from aggregation within an aquatic medium (suspended or bed sediment) and an aggregate is a particle which has resulted from aggregation outside an aquatic environment (e.g. soil particle). Aggregates can be observed and transported within the aquatic environment owing to their delivery to the system by land-surface processes (e.g. stormwater runoff). Flocculation and aggregation will be used interchangeably within this article.

2.2 Particle Size

While the definition of a particle above is based in part on size, a brief discussion of what defines the size of a particle is required based on the methods to be evaluated in this article.
Figure 2 Schematic classification of what environmental science generally considers as dissolved, colloidal and particulate compounds as defined by size and organic and inorganic components. All of the components to the left of the flocculation wedge can be incorporated into flocculated or aggregated particles with a subsequent increase in effective size. No upper size range for floc size can be determined as it is dependent on a number of physical, chemical and biological factors, although marine snow has been observed in the order of centimeters. (Modified with permission from J. Buffle, D. Perret, M. Newman, ‘The Use of Filtration and Ultrafiltration for Size Fractionation of Aquatic Particles, Colloids and Macromolecules’, in Environmental Particles, eds. J. Buffle, H. van Leeuwen, Lewis Publishers, Chelsea, MI, 1992. Copyright, CRC Press, Boca Raton, FL.)

Convention dictates that most methods of particle sizing provide results in terms of particle diameter (or a range of possible diameters). In nature and in most industrial processes, particles are, however, not geometrically perfect spheres, squares, or the like, but rather constitute irregularly shaped particles. This is particularly true for flocs where the particles are not only irregular in shape but also in composition and density. Such complexity requires that an equivalent diameter be measured or derived from a given technique. Allen provides 13 different measures of particle diameter which are based on one or all of the following physical characteristics of (1) the particle (e.g. volume, surface area), (2) the suspension (density and viscosity of the fluid relative to the particle during settling) and (3) the filter (pore size). As this article focuses only on filtration and optical size determination, particle size will be defined as follows:

Filter Particle Diameter: the width of the minimum aperture through which a particle will pass. In reality, however, filtration only provides a particle size range and not an estimate of discrete particle size (unless assessed optically under a microscope). A given filter will, therefore in theory, retain all particles on or within a filter whose particles are larger than the nominal or average pore size of the filter.
Optically Derived Equivalent Spherical Diameter: optical size determination of sediment sizes retained on a filter or in a plankton chamber is represented as a distribution of equivalent diameters. That is, the diameter of a sphere whose cross-sectional area is equal to the projected area of the particle.

2.3 Filtration

Filtration can be defined as the separation of solid particles from a liquid or gas by passing the mixture through a porous, fibrous or granular substance. In science and most industrial processes, filtration is most commonly used for the concentrating of particulate matter or for the separation of particles into size classes through sequential or cascade filtration for subsequent physical, chemical or biological analysis. Separation of particles into multiple size classes is also commonly used for the determination of grain size distributions (derived through a mass-balance approach). There are several mechanisms by which particles are removed from a given medium during filtration. These are as follows:

Interception: occurs when a particle moving within a flow streamline comes in contact with the surface of the filter. Interception is most important when the ratio of particle diameter to the pore size is relatively large. The importance of this mechanism increases as filter clogging or caking occurs. Modeling efforts have shown that for particles larger than 1 µm, interception is the main mechanism of particle removal suggesting that retention is a function of filter geometry and particle size and is independent of particle density, diffusivity, particle settling velocity and fluid velocity.

Inertial Collection: occurs when the flow streamline bends around a filter fiber or within a pore, but the inertia of the particle keeps it on its original track so that it impacts the filter surface. This mechanism is most important when the flow velocities are high and when fiber filters are employed.
Brownian Diffusion: occurs primarily with colloidal particles (<0.5µm). There is an inverse relationship between the importance of this mechanism and particle size. Particles follow the flow stream to the surface of the filter where the concentration is initially zero. This mechanism works best with low flow rates as the time spent by a colloidal particle in the vicinity of the filter surface increases, resulting in enhanced diffusional removal.

Electrostatic Deposition: occurs through electrochemical attractions between the filter and the particle. This can be important for colloidal particles; however, it is generally neglected unless the particles or filters have been charged in some quantifiable way.

Gravitational Settling: generally gravitational settling is insignificant during filtration in aqueous media as the ratio of particle terminal settling velocity to the free stream velocity is small. This mechanism will only be important for very large particles which are above the range discussed in this article.

These mechanisms (excluding electrostatic deposition and gravitational settling) have been reviewed as related to modeling of filtration processes by Logan and Logan et al. Filtration models can be used to determine whether samples should be filtered in series or in parallel and to determine the appropriate filter types and pore sizes for different applications related to particle sampling and sizing. The actual mathematical modeling of filtration is beyond the scope of this article.

3 EQUIPMENT

3.1 Filter Types

There are numerous reviews of filter types, structures, compositions and applications. Filters consist of either tightly woven fibrous mats of natural or synthetic materials or plastic porous membranes. Consideration as to what type of filter to use for a specific application in particle characterization requires a knowledge of a number of factors including cost, availability, collection efficiency, compatibility with the analytical and sampling procedures, compatibility of the filter pore size with the sample particle size range, the ability to remove particles for analysis following filtration, chemical inertness and sterilization considerations. Many filters (particularly membrane), depending on their composition and the digestion procedure used, can be digested along with the sediment for chemical analysis. If the filtrate is to be analyzed for the “dissolved” phase, care must be taken to choose the best filter type as this can have a profound effect on the filtrate chemical characteristics. Filters come in a number of different sizes and formats. Cartridge filters, commonly used in industry, will not be discussed here as they are not appropriate for the sizing of particles. Commonly used filter media are listed below, with the general physical characteristics of each filter type given in Table 1 and environmental scanning electron micrographs of the surfaces of these filter types in Figure 4(a–d). For the purposes of this article, all separation media described will be referred to as filters although many can and are also called screens, nets or sieves.

Screens, nets or sieves are generally used for larger size particle separation and are basically a weave of usually nylon fibers with pore shape dictated by the nature of the weave (e.g. Nitex™). A number of different weaves are available, the square weave (square pores) being one of the most common.

Fibrous filters (depth filters) are tightly woven mats of materials such as glass, cellulose (paper), quartz, silk, polyester, rayon or plastic fibers. These filters are relatively inexpensive, widely available (e.g. Whatman™ paper filters) and have high flow rates and high collection efficiencies for a wide range of particle sizes, with the cellulose filters appropriate for high-temperature ashing. They are not appropriate if the retained sediment is required to be removed from the filter prior to analysis, particularly if the sample is dominated by cohesive sediments. This is primarily due to the entrapment of sediments within the filter mat and the large surface roughness relative to the diameter of the particles. These filters are primarily used for clarification and removal of large particles. Often depth filters are used as prefilters in order to reduce clogging of membrane filters. Chemical inertness is questionable with regard to glass and quartz fiber filters as metal ions are strongly adsorbed, while the affinity of organic to quartz fibers can result in an overestimation of organic carbon concentration and mass.

Membrane filters are porous membranes, such as Millipore™, composed of cellulose nitrate and cellulose triacetate (less common compositions are PVC, nylon, Teflon™ and silver). Teflon™ should be used for chemical studies as it is the most chemically inert although it cannot be used for analyzing organic species. Filtration on membrane filters results in the particles concentrating at or close to the surface of the filter. Unlike the fibrous filters, a membrane filter’s loading capacity is limited. High pressure gradients are possible with resultant particle deformation.\textsuperscript{21,23,35}

Polycarbonate pore filters (Nuclepore™) are smooth, sheet-like filters with cylindrical pores perpendicular to the surface of the filter.\textsuperscript{21,23,35} Particles are collected at the surface of these filters, making them appropriate for particle wash-off for subsequent analysis (provided enough sample volume can be obtained) or microscopic observations and sizing of particles in the least disturbed state (albeit some particle flattening may occur of non-rigid particles such as flocs). These filters have a much smaller total void volume (porosity) and hence a lower flow rate than the other types of filters. Like other membrane filters, Nuclepore™ filters have a small load capacity before clogging occurs and high pressure gradients can result in particle deformation.\textsuperscript{21,23,35}

3.2 Filtration Apparatus

While filtration apparatus is available in a number of different formats, generally at a minimal cost relative to other particle separation and sizing methods, to support a number of different filter types and sizes, they all generally consist of standard components. The most commonly used apparatus is a Millipore™-type filtration funnel that supports a 47-mm or 25-mm diameter filter. While larger apparatus are available to support filter sizes up to 30 cm in diameter, these types of apparatus are generally used for particle removal and solute analysis rather than for particle size analysis.\textsuperscript{38} The type of apparatus used is
dependent on the requirements of the study and may be dictated by such factors as volume to be filtered, chemical requirements [stainless steel or plastic (generally polyethylene)], biological requirements (autoclavable or sealed units) and pressure restrictions. Often samples will be pretreated by processing the sample through a sieve (often 100 mesh, 0.15 mm) to define the particle size upper limit for filtration. A filtration system generally consists of the following components as illustrated in Figure 5 (only vacuum filtration is illustrated):

1. **funnel**: reservoir above the filter to hold the sample to be filtered, to allow for measurement of volume filtered and to provide a positive seal around the perimeter of the filter (can be plastic, Teflon™, glass or stainless steel);

2. **filter holder**: to hold the filter securely and to provide a positive seal around the perimeter of the filter (can be plastic, Teflon™, stainless steel or fritted glass);

3. **filtrate collection flask**: composition irrelevant for particle sizing; however, if the solute is to be chemically analyzed then consideration needs to be given to the makeup of the flask;

4. **source of vacuum/pressure**: electric, hand pump or water flow suction;

5. **supporting materials**: sieve for upper size class definition (composition important if chemical characterization is planned), spring clamp, stoppers, filtration hosing, filter tweezers (generally Teflon™ tipped), squirt bottle and overflow protection flask (optional).

### 3.3 Sequential (Cascade) Filtration Apparatus

As the term implies, sequential filtration is simply the method whereby the sample is passed through a series of filters in descending order of nominal pore size. This process may be performed in a discontinuous fashion (i.e. one filter at a time) or in a continuous fashion with the filters stacked. Such methodologies have been described by Laxen and Harrison, Tessier et al., de Mora and Harrison, Rao and Kwan, Buffle et al., and Droppo et al. and are depicted in Figure 6 (pore sizes indicated from Droppo et al.) and would be considered to be filtration in series. This method may be modified by performing particle separation in parallel, that is, splitting a sample into the number of filters used, running a sample through its respective filter, and then determining grain size distributions by subtracting cumulative masses from consecutive filter retained masses (in descending order).

![Figure 5](Image)

**Figure 5** Generic filtration apparatus components. Note that component size, shape, material and configuration will vary.

![Figure 6](Image)

3.4 Plankton Chamber

If the investigation is concerned only with obtaining a particle size distribution which is representative of the “true” size of the particles within a natural or engineered system, then the use of plankton chambers in conjunction with image analysis is recommended over filtration.

The plankton chamber (Hydro-Bios Kiel®) consists of four components (Figure 7): (a) a 3 mL reservoir with removable circular microscope slides in which the specimen comes to rest after settling, (b) a column available in various volumes (10, 25, 50 and 100 mL), (c) a top cap used to hydrostatically seal the plankton chamber and (d) a square piece of glass used to cover the reservoir after the column has been removed. In this technique the particulate sample may be introduced to the column section of the plankton chamber, either by a wide-mouth pipette (>3 mm) or the suspension can be sampled directly within the plankton chamber set up as described by Droppo and Ongley.\(^{(45)}\) In general, within the field the appropriate column (Figure 7) volume is placed under the water and parallel to the direction of flow. The column is then capped under water and inverted upright for floc settling and subsequent observations such as that illustrated in the upper part of Figure 7. The size (volume) of the column used is dependent on the ambient suspended solids concentration (Droppo and Ongley,\(^{(45)}\) provide a curve relating recommended column volumes to ambient concentration). Once sampled, the particles/aggregates/flocs settle under gravity until they come to rest on the microscope slide portion of the plankton chamber. Once at rest, the sample can be sized using an inverted microscope interfaced with any image analysis system capable of measuring particle size distributions. (There are many commercially available computer image analysis systems on the market spanning a wide range of price. These systems will not be discussed here.) Problems associated with the use of plankton chambers is that they are relatively expensive compared with standard filtration methods and the technique is concentration limited (also true for the optical analysis of particles on filters).\(^{(1,45)}\)

4 PARTICLE SIZING BY FILTRATION

For the effective separation of particles into size classes by filtration, three criteria must be met:\(^{(41)}\)

1. the stated filter nominal porosity must approximate the effective or experimentally observed porosity;
2. the filter pores should have a relatively uniform size;
3. the effective pore size should remain relatively constant throughout the filtration procedure.

Very rarely, if at all, are all of these criteria met during filtration. Several studies have concluded that cellulose acetate membrane filters (Millipore\(^{(9)}\)), glass-fiber filters and silver filters do not satisfy the above requirements.\(^{(20,46,47)}\) Generally, it is found that Nuclepore\(^{(44)}\) filters provide the best separation, although there are still material and methodological problems, as discussed below. In general, sizing of particles by filtration is poor in relation to the nominal pore size specifications. The poor performance of filters used in experimental settings has been reported by Logan\(^{(30)}\) and Droppo et al.\(^{(43)}\) Logan\(^{(30)}\) has shown that as many as 8% of the number of particles and 50% of the mass can be retained on a 210 μm (pore diameter) polypropylene filter even though all of the particles were <100 μm. Likewise, Droppo et al.\(^{(43)}\) have shown, for sequential filtration, errors as high as 60% of the sediment (by volume) isolated by filtration being below the targeted nominal pore size of the filters (60–10 μm nylon mesh). As such, the stated
nominal pore size cannot be used as a definitive cutoff for targeted size classes; however, further experimentation or modeling may provide the user with an acceptable pore size and filter type for a given targeted size range.

As implied above, of all the methods of particle sizing, filtration is likely to be one of the most problematic and potentially inaccurate methods and yet if precautions are taken, and potential errors are realized, it can also be one of the most useful as it is one of the few methods in which particles can be physically separated into designated size classes for subsequent analysis. In addition, it lends itself to optical applications which can be very accurate and provide visual confirmation of particle size, composition and texture. The problems around filtration are based primarily on (a) the physical aspects of the filters, (b) the nature of the particles to be separated and (c) the procedure used for filtration. These problems and possible error controlling measures are discussed below.

4.1 Effect of Physical Aspects of Filter

The efficiency by which various filter types separate particles into targeted size classes based on their nominal pore size has most often been assessed with retention curves (Figure 8a–d). The size range covered by the plots represents the width of the pore size distribution, while the median pore size (the effective pore size) is represented by the 50% value. The steeper the slope of the line, the more selective the filter’s performance is. Figure 8(a–d) suggests that Millipore and Whatman glass-fiber filters have the greatest selectivity with Nuclepore and Flotronics filters having poorer selectivity. Figure 9 shows that there are great differences between the effective pore size and the nominal pore size of the various filters as stated by the manufacturers. The Flotronics and Nuclepore membrane filters show a reasonably close 1:1 relationship (i.e. sharpest separation in the median pore size) whereas the Millipore (cellulose) filters showed similar effective pore sizes irrespective of the nominal pore size (i.e. poor separation at the median pore size) (the Whatman glass-fiber filters had effective pore sizes all below 1.0 µm). Given these results, glass-fiber and cellulose membrane filters are not recommended for separating particles by size. This is primarily because fiber filters have a wide array of pore sizes and tortuous flow paths which result in the trapping of particles within the filter bed. Because Nuclepore filters act more like sieves, these appear to be the best filters for particle fractionation and grain size distribution analysis below 8 µm. Nylon mesh such as Nitex can also be effective for larger particle size separation (see Table 1), although errors were also found by Droppo et al. for these and Nuclepore filters. However, it should be realized, given that most retention curves for calibration purposes are based on measurements made with particle size standards or beads of known size, shape and density (to avoid the issue of aggregation), or on low-concentration highly defined natural samples, it is unlikely that the retention curves in Figure 8(a–d) bear any resemblance to a filter’s performance when environmental/industrial flocculated cohesive particles are filtered. This is primarily related to increased pore clogging by such particles (see below).

Filter clogging is primarily a function of the nature of the filter (specifically material and pore structure) and of the nature of the particle (see below) and is probably the most significant problem associated with filtration in causing the greatest associated errors in particle sizing. As a filter becomes overloaded, fiber width increases and pore size decreases. For polycarbonate filters, clogging is initiated through surface coagulation and pore clogging by aggregates larger than the pore size. This has the effect of reducing the flow rate and increasing the removal efficiency by widening the band of particle selectivity (i.e. smaller particles are trapped). This problem can be to the extreme as “dissolved” and colloidal materials or elements can be removed by filtration. Polycarbonate filters will clog faster than a cellulose membrane filter owing to their more defined singular pore structure. The problems of filter clogging can be avoided by stopping filtration at signs of reduced flow rate, by not reusing filters, using a larger diameter filter (larger surface area per unit volume filtered), by minimizing the volume of sample fractionated per filter, by diluting the sample to minimize particle–particle interactions (if chemically acceptable), by insuring a low flow rate and, if instrumentation allows, by keeping the sample above the filter stirred. (If bulk removal is the goal of the procedure, then filter clogging is not an issue.)

4.2 Effect of Nature of the Particles

Different particles will have different sticking coefficients and the higher the coefficient the greater is the potential for surface coagulation and pore and fiber clogging. The importance of the sticking coefficient relative to filtration will vary depending on the filter material, the particle type (cohesive or non-cohesive) and solution characteristics such as ionic and organic concentrations. The influence of particle type on filter performance is compounded by the majority of cohesive sediment generally existing in a flocculated state. The rheology of flocculated sediment has been described as plastic, and, as such, flocs will deform (flatten) on
to the filter surface or into pores or fiber spacing, increasing the potential of filter clogging. If the filter is to be examined optically for the determination of particle size, then any deformation of the particles is undesirable. The use of plankton chambers, discussed in section 3.4, is recommended for providing an estimation of particle size distribution with a minimum of particle size distortion.

4.3 Effect of Procedure Used for Filtration

4.3.1 Effects of Sequential Filtration Procedure

Although there appears to be no significant difference in the resultant grain-size distribution derived between serial or parallel sample processing, there are serious grain-size errors associated with the sequential filtering.
clogging is accentuated as pore size decreases$^{(20,43)}$ and sticking coefficients increase.$^{(30)}$ Targeted size classes cannot be derived from the nominal pore sizes of the filters.

### 4.3.2 Effects of Sample Volume

While the amount of sediment to be filtered out of solution will be dictated by the analysis to be performed on the sediment, the smallest sample volume should be used in order to avoid overloading the filter, resulting in clogging and resultant inaccurate chemical and particle sizing as discussed in section 4.1.$^{(20,47,48)}$ When large-volume filtrations are needed, frequent filter changes and/or large area filters should be used.

### 4.3.3 Effects of Filter Pressure and Flow Rate

Although Sheldon$^{(47)}$ found that the degree of vacuum had no effect on the retention characteristics of various types of filters, a working rule when using filtration for particle size analysis is that, when possible, only gravity filtration should be performed. However, when positive or negative pressure is required, the lowest pressure or vacuum possible is preferred (below 0.17–0.3 atm)$^{(20,47,49)}$ In so doing, there is a minimization of the erroneous effects of particle breakup and deformation (flattening) at the filter surface$^{(43,47)}$ and filter clogging is also minimized by reducing the rate of particle trapping (especially by inertial collection).

The degree of vacuum or pressure is also related to the flow rate and, as such, a low flow rate is also desirable. This is particularly true for small particle sizes and colloids. Buffle et al.$^{(20)}$ have shown that for colloidal particles, there is a narrow window flow rate and storage time at which separation is optimized. If the flow rate is too fast (i.e. the residence time of the solution above the filter is too short), then variability in the particle sizing result is greater owing to filtration conditions and the nature of the membrane. If, on the other hand, the flow rate is too slow and the residence time too long, then variability is a function of storage conditions and particle nature.

### 4.3.4 Effect of Stirring

Whereas Laxen and Chandler$^{(49)}$ found that sample stirring had no benefits for Sartorius$^{20}$ or Nuclepore$^{20}$ filters, many have suggested that stirring the sample in the filtration reservoir while filtering helps to keep an even distribution of particles in suspension above the filter and reduces any concentration polarization that may occur between particles and the filter surface.$^{(20,21)}$ Stirring will have the greatest positive effect for the colloidal fraction of particles. If stirring is not applied then particles concentrate close to the filter surface and coagulation and associated filter clogging can occur at a faster rate.$^{(48)}$ Too
4.3.5 Effect of Field Sampling
Filtering in the field, as opposed to filtering in the laboratory following sample transport/storage, will generally provide more accurate grain size results.\(^{(20,49)}\) This is related to (a) minimizing aggregation within sample containers during storage and (b) minimizing chemical reactions brought about by changes in oxygen content, pH, ionic interactions and particle–particle interactions, which can affect the particle size distribution and chemical concentrations. This is primarily a result of precipitation, coprecipitation (often through oxidation) and adsorption...
or desorption of ions. Sampling in the field is ideally suited to the direct observation of sediment by using plankton chambers as no sample manipulation is required (see section 3.4). Once the particles are at rest on the microscope slide, they do not move or distort and can then be transported to the laboratory for subsequent direct observation, microscopic analysis and imaging.

5 QUALITY ASSURANCE OF PARTICLE SEPARATION RESULTS

The quality assurance or validation of the accuracy of particle separation may be assessed through a number of technical procedures or through some simple approaches. Which approach to use is dependent on cost, availability of equipment, time of filtration and the nature of the experiment. As most artifacts from sample preparation, handling or filtration will result in an increase in the retention of particles on a filter, conditions which benefit the passage of solute and particles below the targeted size range should be considered as promoting the most realistic results. Buffle et al.\(^{20}\) provide an excellent summation of the approaches that can be used to evaluate the reliability of filtration results. These are as follows:

1. **Flow-rate and Filtration Pressure**: flow rate and therefore filtration pressure should remain constant and independent of retention. Flow rate can be maintained at constant pressure by using a valve at the output of the cell.

2. **Stirring**: retention must be independent of stirring rate.

3. **Filtrate Concentration**: filtrate concentration should be constant during filtration as an indication of no filter clogging. This is one of the most effective methods of evaluating filtration as it is more qualitative than subjective visual inspection of filter caking.

4. **Microscopy**: microscopic examination of filters can be a very powerful tool in providing evidence of selectivity of filters relative to the grain size retained.

5. **Electrolyte Nature and Concentration**: although not discussed in this article [see Buffle et al.\(^{20}\)] this may influence diverse processes relevant to filtration and therefore, separation results. Generalization of this effect is difficult and its effects should be tested for each application.

6 ALTERNATIVE PARTICLE SIZING BY OPTICAL IMAGE ANALYSIS

If the investigation only requires an accurate determination of grain size distribution, then filters can be observed through a standard microscope interfaced with an image analysis system. Such a method of particle sizing, however, has the potential to impart a number of artifacts within the results (although it is likely to be more accurate than that derived from mass-balance analysis using sequential filtration). These distribution artifacts arise from the following: (a) pressure filtration resulting in the deformation of flocculated particles either by disaggregation, aggregation, flattening or burying within pores; (b) particle morphological changes due to filter drying (drying of the particles (flocs) will result in morphological changes as many of these flocculated particles are over 90% water; as such, significant shrinkage can occur with concomitant influences on particle sizing results); and (c) particle morphological changes due to the need to make the filters transparent by the application of an oil such as paraffin or microscope immersion oil. Such an application of highly viscous material will in itself promote morphological changes and also a rehydration of particles with unknown effects. It is for these reasons that, if only a grain size distribution is required, the plankton chamber approach to particle sizing is preferred over filtration. The use of gravity settling on to the inverted microscope slide embedded within the plankton chamber allows the examination of particles in their natural state (hydrated) without the destructive manipulations possibly resulting from filtration. Furthermore, this technique allows the stabilization of flocs in agarose with minimal structural disturbance for their examination (single plankton chamber sample) by multiple microscopic techniques (conventional optical microscopy, scanning confocal laser microscopy and transmission electron microscopy).\(^{44,51}\) Modification of particle structure in any way should always be avoided where possible as it will no doubt have a profound effect on particle size distributions or on other floc characteristics such as fractal dimensions.

DISCLAIMER

Information regarding equipment and the mention of trade names or commercial products are meant as a guide and should not be construed as an endorsement of any particular device or product.

ACKNOWLEDGMENTS

The author would like to thank Dr Gary Leppard for his insightful review of the manuscript. M. West performed the microscopy for the micrographs in Figure 4.

The use of classical, or time-averaged, light scattering methods to characterize the size and size distribution of macromolecules in dilute solutions or particles in dilute dispersions is discussed. The necessary scattering relations are presented systematically, starting with three cases at infinite dilution: the scattering extrapolated to zero angle, the scattering at small angle, and the scattering for arbitrary angle, including the inversion of the scattering data to estimate the size distribution. The relationships needed to effect an extrapolation to infinite dilution from data on dilute solutions are also discussed. These are followed by remarks on light scattering methods, and the concluding sections give examples for several applications. The Rayleigh–Gans–Debye (RGD) approximation is usually appropriate in the scattering from dilute polymer solutions and is also adequate for the scattering from dilute dispersions of small particles. The approximation is assumed when appropriate, but more complete theories are introduced where necessary, as in the use of the Mie–Lorentz theory for large spherical particles.

1 INTRODUCTION

Classical, or time-averaged, light scattering methods are well suited to characterizing certain properties of macromolecules in dilute solutions or particles in dilute dispersions. This technique goes under a variety of names, including static, elastic, integrated and absolute scattering. Information on the size and size distribution may be obtained, and in some cases, it may be possible to elucidate the shape of the macromolecule or particle. The theory and practice of such measurements is well represented in reviews and monographs, providing the basis for this article. In addition to these, very useful compilations of original papers are available on the scattering from macromolecules and particles. In the following, the scattering relations are presented systematically, starting with three cases at infinite dilution: the scattering extrapolated to zero angle, the scattering at small angle, and the scattering for arbitrary angle. The relationships needed to effect an extrapolation to infinite dilution from data on dilute solutions are then discussed. Remarks on light scattering methods follow, and the concluding sections give examples of several applications. As discussed below, the RGD approximation is usually appropriate in scattering from dilute polymer solutions and is also adequate for scattering from dilute dispersions of small particles. It will be assumed for much of the following, but more complete theories will be introduced where necessary, as in the use of the Mie–Lorentz theory for large spherical particles.

2 SCATTERING RELATIONS
2.1 General Remarks

Classical, or static, light scattering refers to an experiment in which an intensity $I(\vartheta)$ is determined at a scattering angle $\vartheta$ by averaging the fluctuating intensity of the light scattered from a material over a time long compared with the timescale of the fluctuations.
The temporal character of the fluctuations is studied in dynamic light scattering \(^{(1,6,10,17,27)}\) (also see Chu \(^{(7)}\) p. 243) a subject outside the purview here. For dilute solutions of macromolecules, or dispersions of particles, the averaged intensity carries information on the intramolecular properties of the molecular weight \(M\), mean-square radius of gyration \(R_G^2\), and mean-square molecular optical anisotropy \(\delta^2\), as well as the intermolecular property of the second virial coefficient \(A_2\), and possibly higher order virial coefficients and intermolecular interference phenomena. Furthermore, for polydisperse systems, the data may also permit assessment of any structural distribution (e.g. molecular weight, size, or possibly shape, of a dissolved molecule or dispersed particle). The reader should be forewarned that owing to its history and variety of applications, the nomenclature in light scattering varies among authors (e.g. see Kerk,\(^{(21)}\) p. 60). In the interests of consistency, the nomenclature used herein will follow that used previously by the author,\(^{(1,4,10,18)}\) and where appropriate these sources will be cited for further detail in addition to, or in lieu of, citations to the original literature referenced therein.

In general, it is not necessary to distinguish between solutions of macromolecules or dispersions of particles in discussing the fundamental relations for scattering, and the following applies to either case. For convenience, both macromolecules and particles will be referred to as the solute. In most experimental arrangements of interest here, the scattered intensity in the scattering plane, the plane containing the incident and scattered beams, is determined as a function of \(\theta\), or modulus \(q = (4\pi/\lambda)\sin(\theta/2)\) of the scattering vector, with \(\lambda = \lambda_0/n_{\text{medium}}\), where \(n_{\text{medium}}\) is the refractive index of the solution, \(\lambda_0\) is the wavelength of the incident light in vacuo, and \(\theta\) is the angle between the incident and scattered beams. Often, the electric vector of the incident light is plane polarized perpendicular to the scattering plane, and this arrangement will be presumed in the following, unless otherwise specified. The scattered light intensity is monitored through a photomultiplier or other photonic sensitive device, either as an analog signal or a digital photon count rate. In either case, an instrument response \(G(\theta)\) at angle \(\theta\) is determined, with \(G(\theta)\) proportional to the time-averaged intensity \(I(\theta)\) of the scattered light. The latter is used to compute the Rayleigh ratio \(R(\theta)\), given by \(r^2I(\theta)/V_{\text{INC}}\), with \(r\) the distance between the scattering centers and the detector, \(V\) the scattering volume, and \(I_{\text{INC}}\) the intensity of the incident light; \(R(\theta)\) is often called the differential scattering cross-section in the physics literature (see Bohren and Huffman,\(^{(13)}\) p. 383). The ratio \(R(\theta)/G(\theta)\) may be determined by an appropriate experiment for a given arrangement (also see Chu,\(^{(7)}\) p. 243).\(^{(1,10,18)}\) The following section will discuss the information that may be obtained in order to characterize the solute in a solution (or dispersion) by analysis of \(R(\theta)\) under various conditions.

The excess Rayleigh ratio for the solution with concentration \(c\) of solute, less that due to the solvent, is usually the property of interest. This is normally calculated as \(R_{\text{scat}}(\theta, c) = R_{\text{SOLN}}(\theta, c) - R_{\text{SOLVENT}}(\theta)\), but alternative estimates of \(R_{\text{scat}}(\theta, c)\) may be required for very low-molecular-weight solute.\(^{(28)}\) The subscripts `xs', etc. will be suppressed throughout, and \(R(\theta, c)\) will imply the excess quantity. Here, \(c\) is the weight of the solute per unit volume of the solution. Alternatively, the number of molecules \(v\) per unit volume of the solution is sometimes used, especially in theoretical work; \(v = cN_A/M_n\), with \(M_n\) the number average molecular weight determined, for example, from colligative properties, and \(N_A\) Avogadro's constant (see Flory,\(^{(29)}\) p. 273). It may be noted that the scattered intensity in discussions of the scattering from particles is sometimes expressed in intensity units per particle per volume, with an implied factor \(v\) omitted, for example these units are used in two well-known monographs focussed on the scattering from particles.\(^{(21,22)}\)

The notation \(R_{\text{Scat}}(\theta, c)\) will be used in the following to designate the polarization states of the scattered and incident light rays, where subscripts \(s\) and \(i\) will designate the polarization of the electric vectors of the scattered and incident light, respectively, relative to the scattering plane. Thus, for vertically polarized incident light, and horizontally or vertically polarized scattered light, respectively, the observed scattering may be expressed as Equations (1) and (2),\(^{(4,10)}\)

\[
R_{\text{He}}(\theta, c) = R_{\text{aniso}}(\theta, c)
\]

\[
R_{\text{Vv}}(\theta, c) = R_{\text{iso}}(\theta, c) + \left(\frac{4}{3}\right) R_{\text{aniso}}(\theta, c) + R_{\text{cross}}(\theta, c)
\]

where \(R_{\text{He}}(\theta, c) = R_{\text{iso}}(\theta, c)\) for an optically isotropic scatterer, and \(R_{\text{cross}}(\theta, c)\) is a cross-term that vanishes for an optically isotropic solute or for \(\theta = 0\). The functions \(R_{\text{iso}}(\theta, c)\) and \(R_{\text{aniso}}(\theta, c)\) are discussed in the following sections. The Rayleigh ratio \(R_{\text{He}}(\theta, c)\) is discussed below, but in the RGD regime, \(R_{\text{He}}(\theta, c) = R_{\text{Vv}}(\theta, c) \cos^2(\theta)\). In much of the older work, written prior to the advent of lasers as a commonly used source of the incident light, an unpolarized (or natural) incident beam is assumed, e.g. comprising equal components of plane-polarized light with electric vectors in the vertical and horizontal directions. Consequently, the Rayleigh ratio for light with electric vector in the vertical direction might be denoted \(R_{\text{Vv}}(\theta, c)\) in such a case, with \(R_{\text{Vv}}(\theta, c) = R_{\text{Vv}}(\theta, c)/2\) for an isotropic solute (with \(R_{\text{Vv}}(\theta, c) = R_{\text{Vv}}(\theta, c) = 0\)) if the total intensity of the incident beam is used in the calculation of each.
In most of the discussion the RGD approximation will be assumed, but this constraint will be relaxed where necessary, e.g. in the use of the complete Mie–Lorentz scattering theory for large spheres (Bohren and Huffman, \textsuperscript{(13)} p. 158; Kerker, \textsuperscript{(21)} p. 414; van de Hulst, \textsuperscript{(22)} p. 85). In the RGD approximation, the scatterer is treated as an assembly of scattering elements which scatter radiation independently of all other elements. The elements are taken to represent the smallest unit that both gives a unique refractive index tensor and for which interference effects are negligible for rays scattered from a single element, e.g. the elements are independent Rayleigh scatterers (see Chu, \textsuperscript{(7)} p. 14; Bohren and Huffman, \textsuperscript{(13)} p. 7; Kerker, \textsuperscript{(21)} p. 414; van de Hulst, \textsuperscript{(22)} p. 86).\textsuperscript{(16,18)} An important property in the RGD approximation that is used in much of the following is that the optical contrast factor can usually be considered to be independent of the size or shape of the scatterer, depending only on its composition relative to that of the medium. This allows a factorization to be assumed in much of the following for which the RGD approximation is utilized, but which must be abandoned if that approximation cannot be used. Use of the RGD approximation greatly facilitates the discussion of the effects of heterogeneity of the scatterers, permitting analytical representations of certain averages for properties determined by analysis of \( R_{xy}(\theta, c)/c \) and \( R_{xyc}(\theta, c)/c \), as discussed in the following. The RGD approximation fails as the phase shift of the light within an individual scatterer domain becomes too large, see below.

In most cases, the discussion will be couched in terms of the weight fraction \( w_a = c_a/c \) of scattering components distinguished by some characteristic, e.g. molecular weight, shape, optical contrast relative to the supporting medium, etc. with overall concentration \( c = c_p \). As discussed below, \( [R_{xy}(\theta, c)/c]_0 \) reduces to a constant under certain conditions, but in general, this ratio depends on \( M, c \) and \( \theta \), reflecting interference effects from the scattered rays from different scatterers, as well as the particular characteristics of the individual scatterer. Of course, similar expressions may be written for \( R_{xyc}(\theta, c) \).

It is convenient to express \( R_{iso}(\theta, c) \) in the form of Equations (3) and (4),\textsuperscript{(4,10)}

\[
\begin{align*}
R_{iso}(\theta, c) &= K'\psi_{solute}^2 M_{LS} S_{iso}(\theta, c) c \\
S_{iso}(\theta, c) &= P_{iso}(\theta, c) F_{iso}(\theta, c)
\end{align*}
\]

where \( M_{LS} \) is the light scattering averaged molecular weight, \( S_{iso}(\theta, c) \) is the structure factor (see more below), \( P_{iso}(\theta, c) \) and \( F_{iso}(\theta, c) \) are intramolecular and intermolecular structure factors, respectively, with \( P_{iso}(0, c) = F_{iso}(0, 0) = 1 \), \( K' = 4\pi n_{medium}^2/N_A\lambda_0^2 \), and \( \psi_{solute} \) a contrast factor; it should be noted that some authors use a notation in which \( F_{iso}(\theta, c) \) would be denoted \( S_{iso}(\theta, c) \).\textsuperscript{(30)} For many cases discussed below, \( \psi_{solute} \) is equal to the refractive index increment \((dn/\text{d}c)_{\text{H}}\) at osmotic equilibrium of solvent components.\textsuperscript{(10,16,18)} For a solute in a single component solvent, \((dn/\text{d}c)_{\text{H}} \approx n_{medium}(\tilde{n} - 1)/n_{solute} \) with \( n_{solute} \) the density of the solute, and \( \tilde{n} = n_{solute}/n_{medium} \), where \( n_{solute} \) and \( n_{medium} \) are the refractive indices of the solute and medium, respectively.\textsuperscript{(31)} This form is also used for a suspension of particles in a gas or vacuum for small \( \tilde{n} - 1 \); a revised expression for large \( \tilde{n} - 1 \) is discussed below (Bohren and Huffman, \textsuperscript{(13)} p. 158; Kerker, \textsuperscript{(21)} p. 414; van de Hulst, \textsuperscript{(22)} p. 85). Here, and in the following, the subscript ‘LS’ designates the average obtained for small \( \tilde{n} - 1 \); a revised expression for large \( \tilde{n} - 1 \) is discussed below (Bohren and Huffman, \textsuperscript{(13)} p. 158; Kerker, \textsuperscript{(21)} p. 414; van de Hulst, \textsuperscript{(22)} p. 85). In light scattering for solute polydisperse in its properties, the nature of that average for particular types of heterogeneity is delineated in the following sections.

In general, for a nonabsorbing isotropic solution, expansion of \( P_{iso}(\theta, c) \) at infinite dilution gives Equation 5):\textsuperscript{(10,18)}\textsuperscript{(10,18)} (see also Kerker, \textsuperscript{(21)} p. 424; van de Hulst, \textsuperscript{(22)} p. 98; Guinier and Fournet, \textsuperscript{(24)} p. 24)

\[
P_{iso}(\theta, 0)^{-1} = 1 + \frac{(R_{iso}^2)_{LS} \sigma^2}{3} + \cdots \tag{5}
\]

where \( (R_{iso}^2)_{LS} \) is the light scattering average mean-square radius of gyration of the scatterers and the notation \( P_{iso}(\theta, 0) \) denotes the function at infinite dilution. In most cases, for optically isotropic scatters, it is useful to express \( F_{iso}(\theta, c) \) as Equation 6):\textsuperscript{(4,10,31)}\textsuperscript{(10,18,31)} (see also Yamakawa, \textsuperscript{(20)} p. 186)

\[
F_{iso}(\theta, c)^{-1} = 1 + c\Gamma_{iso}(c) P_{iso}(\theta, c) H_{iso}(\theta, c) \tag{6}
\]

since in many cases, \( H_{iso}(\theta, c) \approx 1 \). With this representation (Equation 7)

\[
KcM/R_{iso}(\theta, c) = S_{iso}(\theta, c)^{-1} = P_{iso}(\theta, c)^{-1} + c\Gamma_{iso}(c) H_{iso}(\theta, c) \tag{7}
\]

where \( K = K'\psi_{solute}^2 \).

As elaborated below, in most cases, a virial expansion of \( \Gamma_{iso}(c) \) suffices for the scattering from dilute solutions (i.e. solutions with \( cN_A(R_{iso}^2)_{LS}/M_{LS} \ll 1 \)). Equation 8):\textsuperscript{(4,10,31)}\textsuperscript{(4,10,31)} (see also Yamakawa, \textsuperscript{(20)} p. 186)

\[
\Gamma_{iso}(c) = 2(A_2)c_{LS}M_{LS} + 3(A_3)_{LS}cM_{LS}c + \cdots \tag{8}
\]

with \( (A_2)_{LS} \) the light scattering averaged second virial coefficient, etc. The virial expansion may fail for charged scatterers in a solvent with very low ionic strength, so that electrostatic interactions are not shielded (see section 4 for examples).\textsuperscript{(10,16,18,32)} Other forms for \( \Gamma_{iso}(c) \) may be required for moderately concentrated (or semidilute) solutions.\textsuperscript{(3,4,33)} The general interpretation of the functions \( P_{iso}(\theta, c), H_{iso}(\theta, c) \) and the parameters \( M_{LS} \).
where \( \delta / \beta_0 \) is the light scattering averaged mean-square molecular optical anisotropy form factor, \( S_{\text{aniso}}(\theta, c) \) is a structure factor, and \( \psi_{\text{solute}} \) is an anisotropic contrast factor, conveniently expressed as \( \psi_{\text{solute}} / \delta_0 \) if \( \psi_{\text{solute}} \neq 0 \), with \( \delta_0 \) the optical anisotropy of a scattering element, see the section 4, “Examples” below. As above, the factor \( K' \psi_{\text{solute}}^{-1} \) must be modified if the RGD approximation is not valid. A similar set of equations to those for \( S_{\text{iso}}(\theta, c) \) may be written for \( S_{\text{aniso}}(\theta, c) \), with \( P_{\text{iso}}(\theta, c) \) replaced by \( P_{\text{aniso}}(\theta, c) \), etc. In most cases of interest here, \( \Gamma_{\text{iso}}(c) \) is considerably smaller than \( \Gamma_{\text{iso}}(c) \), \( H_{\text{aniso}}(\theta, c) \approx 1 \), and \( P_{\text{aniso}}(\theta, c) \neq P_{\text{iso}}(\theta, c) \), except for \( \theta = 0 \), see below.

2.2 Scattering at Zero Angle and Infinite Dilution

2.2.1 Isotropic Solute in the Rayleigh–Gans–Debye Regime

In this limit, attention is focused on \( [R_{\text{aniso}}(0, c)]^0 \) or \( [R_{\text{iso}}(0, c)]^0 \) below, with the implicit assumption that the extrapolations to zero angle and infinite dilution can be accomplished; these extrapolations are discussed in section 2.6. The superscript “0” indicates the extrapolation to infinite dilution throughout, and unless stated otherwise, it is assumed that \( \psi_{\text{solute}} \neq 0 \), as would usually be the case in applications of interest in light scattering. In this regime, \( S_{\text{iso}}(\theta, c) \) is equal to the parameter \( M_{\text{LS}} \), which as seen above, may be equal to the weight-average molecular weight \( M_w \) under certain conditions, but will often be a more complex function of the properties of the scatterers. Beginning within the RGD approximation, for an optically isotropic solute comprising a number of components, possibly differing in chemical composition, Equations (10) and (11) apply:

\[
M_{\text{LS}} = \frac{R_{\text{aniso}}(0, c)}{K' \psi_{\text{solute}}^2 c} \tag{10}
\]

\[
M_{\text{LS}} = \sum_{\mu} w_{\mu} M_{\mu} \left( \sum_{i} \psi_{m_i} \right)^2 \tag{11}
\]

with \( \psi_i \) and \( m_i \) the refractive index increment and the molar mass of element \( i \), respectively, and \( w_{\mu} \) the weight fraction of components with molecular weight \( M_{\mu} = \left( \frac{m_i}{\mu} \right) \) and identical values of \( \psi_{m_i} \), with \( \psi_{\text{solute}} = w_{\mu} \psi_{\mu} \). Here, the sums over \( i \) extend over all of the scattering elements in molecule (particle) \( \mu \).

If each component is compositionally homogeneous, i.e., has only one type of scattering element, then \( \left( \psi_{m_i} \right)_{\mu} = \psi_{\mu} M_{\mu} \), and Equation (12) follows:

\[
M_{\text{LS}} = \sum_{\mu} w_{\mu} M_{\mu} \psi_{\mu}^2 \tag{12}
\]

In the simplest case, for an optically isotropic, compositionally homogeneous solute, \( \psi_{\mu} = \psi_{\text{solute}} \), and this reduces to the well-known relation, Equation (13):

\[
M_{\text{LS}} = M_w = \sum_{\mu} w_{\mu} M_{\mu} \tag{13}
\]

where \( w_{\mu} \) is the weight fraction of component \( \mu \) with molecular weight \( M_{\mu} \). This simple relation applies to solutions or dispersions in a mixed solvent, provided that \( \psi_{\text{solute}} \) is used, as stipulated above. If the refractive index \( (dn/dc)_w \) determined at constant composition of the mixed solvent is used instead, then, to a good approximation, Equation (14) applies:

\[
M_{\text{LS}} = \frac{(dn/dc)_{\text{mix}}^2}{(dn/dc)_w} M_w \tag{14}
\]

where \( (dn/dc)_{\text{mix}} \) and \( (dn/dc)_w \) are the refractive index increments of a single-component solute. The ratio \( (dn/dc)_{\text{mix}}/(dn/dc)_w \) may be interpreted in terms of preferential solvation of the solute by a component of the solvent. Deviations of \( (dn/dc)_{\text{mix}}/(dn/dc)_w \) from unity are usually most pronounced when the preferentially solvating component is present at low concentration in the mixed solvent.

The more complex relation given above must be used if the solute is optically heterogeneous, as with a copolymer or particles with a spatially varying refractive index. For the special case with only two types of element, characterized by refractive index increments \( \psi_A \) and \( \psi_B \), with \( \psi_{\text{solute}} = w_A \psi_A + (1 - w_A) \psi_B \neq 0 \), Equation (15) applies:

\[
M_{\text{LS}} = M_w + 2Y \sum_{\mu} w_{\mu} M_{\mu} \Delta w_{\mu} + Y^2 \sum_{\mu} w_{\mu} M_{\mu} \left( \Delta w_{\mu} \right)^2 \tag{15}
\]

where \( \Delta w_{\mu} = \left( w_{\mu} \right)_0 - w_{\mu} = w_B - (w_B)_0 \) and \( Y = (\psi_A - \psi_B) / \psi_{\text{solute}} \). Thus, \( M_{\text{LS}} \) is expected to be parabolic in
For example, with the Mie theory for a homogeneous medium, the contrast factor may depend significantly on the modified refractive index, the shape of the scatterer. With this modification, $M_{LS}$ = $M_w$ for a collection of particles with two kinds of scattering element, provided that the composition of each particle is identical to the average composition.

2.2.2 Isotropic Solute Beyond the Rayleigh–Gans–Debye Regime

It should be recognized at the outset that the RGD approximation will almost always be adequate for (nonabsorbing) threadlike macromolecules (e.g. flexible or semiflexible coils, rod-like or helical chains, etc.). This is the case not only at zero angle and infinite dilution, but also for all angles and dilute solutions, owing to the sparse density of the macromolecule in the intramolecular “domain”. Thus, the RGD approximation may be applied, even for a large macromolecule, with an appreciably different refractive index to that of the solvent. The failure of the RGD approximation arises for large particles, under certain conditions elaborated in the following. If the RGD approximation cannot be used, the $|R_{VV}(0, c)/K_{LS}^{solute}|^2$ may still be computed using an appropriate model, but because the scattering may no longer be taken as a sum over independent Rayleigh scattering elements, $\{\psi, m\}_\mu$ for the $\mu$-th scatterer must be replaced by a more complex function. For the discussion of $M_{LS}$, this can be done for compositionally homogeneous scatterers by including a factor $h(\tilde{n}_\mu)$ in $\psi, m$ for the $\mu$-th scattering component, and multiplication of the modified $\psi, m$ by a function $m(\tilde{n}_\mu, \lambda, M)$. Thus, even for chemically homogeneous scatterers differing only in size, the contrast factor may depend significantly on $\tilde{n}_\mu, \lambda, M$, and the shape of the scatterer. With this modification, $M_{LS} = [m(\tilde{n}, \lambda, M)]^2 M$ for a monodisperse solute (with $M_{LS}$ calculated using $\psi, m$ including the factor $h(\tilde{n}_\mu))$.

For example, with the Mie theory for a homogeneous sphere $h(\tilde{n})$ is given by $h_{sph}(\tilde{n}) = 3(\tilde{n} + 1)/2(\tilde{n}^2 + 2)$ (see Bohren and Huffman,[13] p. 158; Kerker,[21] p. 414; van de Hulst,[22] p. 70) and $m(\tilde{n}, \lambda, M)$ may be expressed as $m_{sph}(\tilde{n}, \alpha)$, and calculated as a function of $\tilde{n}$ and $\alpha = 2\pi R/\lambda$; $m_{sph}(\tilde{n}, \alpha)$ reduces to unity as the magnitude of the maximum phase shift $2\alpha(\tilde{n} - 1)$ in the particle becomes small (see Bohren and Huffman,[13] p. 113; Kerker,[21] p. 91; van de Hulst,[22] p. 127). Examples of $M_{LS}/M = [m_{sph}(\tilde{n}, \alpha)]^2$ for monodisperse spheres given in Figure 1 over a range of $\tilde{n}$ and $\alpha$ reveal the complex character of this function, with the possibility that $M_{LS}/M$ may be either larger or smaller than unity. In the use of this figure, consistency is required between $M$ obtained from the determined $M_{LS}$ and the ratio $M_{LS}/M$ and $R = (3M/4\pi p N_A)^{1/3}$ used to select $\alpha$, where $\rho$ is the density of the particle. Deviation of $M_{LS}/M$ from unity is important, for example, in the analysis of the eluent from chromatographic columns by low angle light scattering for large particles, see section 4 below.

It may be noted that the Rayleigh ratio is often not mentioned explicitly in discussions involving the Mie theory, but rather, the theory is developed in terms of scattering amplitude functions $S_i(\vartheta)$, which are the components of the scattering tensor for the scattering from an individual scatterer (see Bohren and Huffman,[13] p. 65; Kerker,[21] p. 47; van de Hulst,[22] p. 47). $S_i(\vartheta)$ is not to be confused with the structure factor $S(\vartheta, c)$ defined above. Reduced intensity functions are computed from the $S_i(\vartheta)$, e.g. for nonabsorbing, optically isotropic scatterers, $i_{VV}(\vartheta) = |S_{VV}(\vartheta)|^2$ and $i_{vh}(\vartheta) = |S_{Vh}(\vartheta)|^2$, with $|R_{VV}(\vartheta, c)/v|^2 = N_A i_{VV}(\vartheta)/k^2$, etc. where $k = 2\pi/\lambda$. For example, $i_{VV}(\vartheta) = i_{VV}(0) P_{VV}(\vartheta, 0)$, with $i_{VV}(0) = 4\pi/(2\pi)^2 = 1/2$ for spherical particles in the nomenclature used here, which reduces to the expected result $|R_{VV}(\vartheta, c)/v|^2 = K_{LS}^{solute} M_{LS}$ for this case (including the factor $h_{sph}(\tilde{n})$ in $\psi_{solute}$).

For isotropic spheres, functions in the Mie theory may be expanded for $\tilde{n} \alpha < 1$ to a give a result (see van de Hulst,[22] p. 45) that may be cast in the form of Equations (16) and (17)

$$m_{sph}(\tilde{n}, \alpha) = 1 + f_{sph}(\tilde{n}) = \frac{\tilde{n} + 1}{[15(\tilde{n}^2 + 2)(2\tilde{n}^2 + 3)]}$$

(17)

for nonabsorbing monodisperse spheres, where $f_{sph}(\tilde{n})$ approaches 44/75 as $\tilde{n}$ tends to unity. As may be seen in Figure 1, this expression provides a useful fit to $m_{sph}(\tilde{n}, \alpha)$ for small $\alpha(\tilde{n} - 1)$, but is generally limited to $\alpha^2(\tilde{n} - 1) < 0.1$ and $\alpha < 1$. In principle, in this range, the deviation from the RGD approximation could be taken into account using the above in expressions for $M_{LS}$ discussed below for the scattering from spheres heterogeneous in $M$.

For nonabsorbing spheres with $\alpha \gg 1$, $i_{VV}(0) = k^2 [R_{VV}(0, c)/v]^2/N_A$ is closely approximated by $(\alpha^2/4) Q_{sca}(\tilde{n}, \alpha)^2$ (see also Kerker,[21] p. 91) where $Q_{sca}(\tilde{n}, \alpha)$ is the extinction efficiency for scattering for spheres at infinite dilution, i.e. $\exp(-\tau)$ is the fraction of the incident light transmitted through a sample with turbidity $\tau = Q_{sca}(\tilde{n}, \alpha) v R^2$, thickness $b$ and concentration $v$. Numerical calculations show that the approximation is quite reasonable for $\tilde{n} > 1.3$ and $\alpha > 4$, with the minimum value of $\alpha$ for which the approximation is useful decreasing with increasing $\tilde{n}$. The abundant literature on the extinction efficiency provides a means to compute $m_{sph}(\tilde{n}, \alpha)$ in this range and has itself been discussed as a means of characterizing size heterogeneity among spherical solutes (see Kerker,[21] p. 351). (39) For example,
be used. For a spherical solute, use of \(m(\tilde{n}, \lambda, M_\mu) = m_{sph}(\tilde{n}, \sigma_\mu)\) gives \(M_{LS} \geq M_w\), but \(M_{LS}\) cannot generally be reduced to an expression involving standard average molecular weights. In the limited range with \(\tilde{n}\sigma_\mu < 1\) discussed above, the approximate expression for \(m_{sph}(\tilde{n}, \sigma)\) may be applied, with the result (for particles of homogeneous refractive index, Equation 19)

\[
M_{LS} \approx M_w + 2 \left( \frac{2\pi R}{\lambda M^{1/3}} \right)^2 j(\tilde{n})|\tilde{n} - 1| M_{SLS}^{5/3}
\]

where \(M_{SLS}^{5/3} \approx M_{LS}^{5/3} M_w\) is defined in Table 1 (for \(\epsilon = 2/3\)). In principle, the dependence on \(\lambda\) embodied in the parameters \(\sigma_\mu\) provides a means of interpreting \(M_{LS}\) (or equivalently, \(Q_{LS}\)) in terms of \(w_\phi\) from the variation of \(M_{LS}\) with \(\lambda\) using the Mie theory to compute \(m_{sph}(\tilde{n}, \sigma)\), after accounting for any dispersion in the refractive indices of solute or solvent. Such a procedure has been the basis of some methods proposed in the literature for characterizing the size of spheres by transmission measurements (see Bohren and Huffman,\(^{13}\) p. 287; Kerker,\(^{21}\) p. 325),\(^{39}\) but these have been largely superseded by methods discussed in the following involving measurements over a range of scattering angles.

### 2.2.3 Anisotropic Solute

For a solute with anisotropic scattering elements, in the RGD regime \([R_{H}(0, c)/K\psi_{\text{solute}} c]\)\(^0\) gives the light scattering-averaged mean-square molecular anisotropy \(\delta_{LS}^{2}\) (with \(\psi_{\text{solute}} \neq 0\)), Equation (20):\(^{10, 46, 41}\)

\[
\frac{R_{H}(0, c)}{K\psi_{\text{solute}} c} \approx \left( \frac{3}{5} \right) M_{LS} \delta_{LS}^{2}
\]

</tr>
</tbody>
</table>

\(a\) For optically isotropic solute, and with \(\sigma_\mu/\epsilon\) the same for all scattering elements.

\(b\) \(M_\mu = w_\mu M^{3/5}\) and \(M_\mu = 1\) \(w_\mu M^{3/5}\); \(M_w = w_\mu M_\mu\); \(M_t = w_\mu M_\mu\); \(M_t = w_\mu M_\mu\).

\(c\) Approximations are for a solute with a Schulte–Zimm (two-parameter exponential) distribution of \(M\), for which \(M_\mu = M_\mu (\Gamma(1 + h + \alpha)/\Gamma(1 + h))^{1/\alpha}/(1 + h)\), where \(h^{-1} = (M_w/M_\mu)^{-1}\), see Berry.\(^{42}\)
For solute with identical, but optically anisotropic scattering elements, \( M_{LS} = M_w \), and Equation (21) applies
\[
\delta_{LS}^2 = \sum_{\mu} w_{\mu} M_{\mu} \frac{\delta_{\mu}^2}{M_w} \tag{21}
\]
Since \( \delta_{LS}^2 \) arises from orientational correlations among the scattering elements, it cannot be interpreted in the absence of a structural model for the scatterer. An example is included below. The expression for \( R_{\psi}(0, c)/K\psi_{\text{solute}}^2 \) for this case becomes (Equation 22)(10)
\[
\frac{R_{\psi}(0, c)}{K\psi_{\text{solute}}^2} = M_{LS} \left\{ 1 + \frac{4\delta_{LS}^2}{5} \right\} \tag{22}
\]

2.3 Scattering at Small Angle and Infinite Dilution

2.3.1 Isotropic Solute in the Rayleigh–Gans–Debye Regime

The ambiguous term small angle indicates that \( \theta \) is small enough that the parameter \((R_G^2)_{LS}\) defined by the equivalent expressions, Equation (23)
\[
\frac{(R_G^2)_{LS}}{3} = \frac{c}{R_{\psi}(0, c)} \left( \frac{\partial[\psi/c]}{\partial q^2} \right)^0 = \frac{\partial \ln[R_{\psi}(\theta, c)c]}{\partial q^2} \tag{23}
\]
may be determined in the limit as \( \theta \) goes to zero, where the superscript "0" indicates that the data are extrapolated to infinite dilution. Thus, for optically isotropic scattering elements, the expansion give above for \( P_{\psi}(\theta, 0) \) may be applied, so that at infinite dilution (averaged over all orientations of the scatterers), in the RGD approximation, Equation (24) follows(1,10,18)
\[
(R_G^2)_{LS} = \sum_{\mu} w_{\mu} M_{\mu}^{-1} \frac{\sum_{ij} \psi(m_i \psi_j m_j (r_{ij}^2))}{2M_{LS} \psi_{\text{solute}}^2} \tag{24}
\]
where \((r_{ij}^2)\) is the mean-square separation of scattering elements \( i \) and \( j \), and \( \psi_{\text{solute}} \neq 0 \). In this expression, \( w_{\mu} \) is the weight fraction of a component with molecular weight \( M_{\mu} \) and common \( (\psi m_i \psi_j m_j (r_{ij}^2))_\mu \), as scatterers with a given molecular weight may differ in composition and/or shape.

For a solute comprising optically identical scattering elements in all components (in the RGD approximation), Equation (25)
\[
(R_G^2)_{LS} = \sum_{\mu} w_{\mu} M_{\mu} \left( \frac{\sum_{ij} (r_{ij}^2)}{2M_w} \right)_\mu = \sum_{\mu} w_{\mu} M_{\mu} \frac{(R_G^2)_\mu}{M_w} \tag{25}
\]
where again, the ensemble may include chains with identical \( M_{\mu} \) but different \((R_G^2)_\mu\), as for a collection of branched and linear chains, all with the same molecular weight. The similarity between this and the expression for the \( z \)-average molecular weight (obtained by replacing \((R_G^2)_\mu\) by \( M_{\mu} \)) often motivates the notation \((R_G^2)_\mu\) for \((R_G^2)_{LS}\) (or \( \Phi \), for any property \( \Phi_{\mu} \) similarly averaged), but that notation may be misleading if \((R_G^2)_\mu\) is not proportional to \( M_{\mu} \) and is not employed here. The parameter \((R_G^2)_\mu\) may be related to the characteristics of the scatterer in this RGD regime, such as the contour length \( L \) and persistence length \( \theta \) of polymer chains, the radius \( R \) of spheres, etc. (see Table 1), or, in some cases, expressed as a power of the molecular weight of the scatterer. Thus, for a solute with the special property that \((R_G^2)_\mu = rM_{\mu}^a\) with \( r \) a constant, the summation gives Equations (26) and (27)\(^{(1,14,22)}\)
\[
(R_G^2)_{LS} = \frac{rM_{\mu}^{a+1}}{M_w} \tag{26}
\]
\[
M_{\mu} = \left( \sum_{\mu} w_{\mu} M_{\mu}^{a+1} \right)^{1/a} \tag{27}
\]
where expressions for \( M_{\mu} \) are given in Berry\(^{(22)}\) for a number of commonly used molecular-weight distributions (e.g. although \( M_{(1)} = M_n \), \( M_{(2)} = (M_n M_z)^{1/2} \) such simple expressions are not possible if \( a \) is not an integer). Expressions for \((R_G^2)_{LS}\) are given in Table 1 for a few cases of interest.

Values of the light scattering averaged hydrodynamic radius \((R_H)_{LS}\) determined by dynamic light scattering are included in Table 1 for comparison. For example, for a random-flight chain \( (\epsilon = 1) \), \((R_G^2)_{LS} = rM_z\), with \( r = \theta / 3M \), and for a rod \( (\epsilon = 2) \), \((R_G^2)_{LS} = rM_zM_{z+1}\), with \( r = (L/M)^2/12 \), where \( M_z \) and \( M_{z+1} \) are the \( z \)- and \( z + 1 \)-average molecular weights. It may be noted that in general, the averages in \((R_G^2)_{LS}\) and \((R_H)_{LS}\) differ.

For an optically isotropic solute discussed above comprising two different types of scattering elements (with \( \psi_{\text{solute}} \neq 0 \), and in the RGD approximation, Equation 28)\(^{(10,36,37)}\)
\[
(R_G^2)_{LS} = x(R_G^2)_A + (1-x)(R_G^2)_B + x(1-x)\Delta_{AB}^2 \tag{28}
\]
for a sample monodisperse in molecular weight, with \( x = w_A \psi_A / \psi_{\text{solute}} \), \((R_G^2)_A\) and \((R_G^2)_B\) the mean-square
radii of gyration of the portions of the solute molecules (particles) comprising only A and type B scattering elements, respectively, and \( \Delta^{2}_{AB} \) the mean-square separation of the center of mass for these portions. The possible dependence of the parameters \((R_{G}^{2})_{A}, (R_{G}^{2})_{B}\) and \( \Delta^{2}_{AB} \) on solvent is neglected herein; this would be expected to be less of an issue with particles than with polymer chains. Expressions are available for \( \Delta^{2}_{AB} \) for certain graft copolymers, and for a solute polydisperse in molecular weight.\(^{36}\)

In some cases \( \Delta^{2}_{AB} \) is zero, simplifying the expression for \((R_{G}^{2})_{LS}\), i.e. alternating copolymers or copolymers with a random placement of monomers, or spheres with a uniform coating (or shell). For block copolymers comprising \( n \) blocks each of A and B chains (e.g. \( n = 1 \) for an AB-diblock copolymer), \( \Delta^{2}_{AB} = 2((R_{G}^{2})_{A} + (R_{G}^{2})_{B})/n \), showing that \( \Delta^{2}_{AB} \) decreases with increasing \( n \), as expected since \((R_{G}^{2})_{LS} = (R_{G}^{2})_{A} = (R_{G}^{2})_{B}\) for an alternating copolymer.\(^{36}\) Inspection of these expressions shows that \((R_{G}^{2})_{LS}\) may bear little resemblance to the geometric mean-square radius of gyration \((R_{geo}^{2})_{LS}\) of the chain, e.g. \((R_{G}^{2})_{LS}\) may be negative, whereas \((R_{G}^{2})_{geo} > 0\). For example, one could construct a diblock polymer or a coated sphere for which \((R_{G}^{2})_{LS}\) is zero, or even negative, though \((R_{G}^{2})_{geo}\) must be positive, see section 4 examples below.

2.3.2 Isotropic Solute Beyond the Rayleigh–Gans–Debye Regime

The preceding expressions must be modified if the RGD approximation fails, as the basic assumption in the RGD model that the scattering from the elements may be added independently for a particle is no longer valid (the reader is reminded that as discussed above, the RGD approximation is almost always adequate for (nonabsorbing) thread-like macro-molecules). For a compositionally homogeneous scatterer (all particles with the same \( \bar{n} \)), Equation (29) applies

\[
(R_{G}^{2})_{LS} = \frac{\sum_{\mu} w_{\mu} M_{\mu} y(\bar{n}, \lambda, M_{\mu}) [m(\bar{n}, \lambda, M_{\mu})]^{2} (R_{G}^{2})_{\mu}^{(RGD)}}{\sum_{\mu} w_{\mu} M_{\mu} [m(\bar{n}, \lambda, M_{\mu})]^{2}}
\]

(29)

where \((R_{G}^{2})_{\mu}^{(RGD)}\) is the value in the RGD regime, \(m(\bar{n}, \lambda, M_{\mu})\) is defined above, and \(y(\bar{n}, \lambda, M_{\mu})\) tends to unity as \(\beta(\bar{n} - 1)\) tends to zero.

With the Mie theory for a compositionally homogeneous sphere, for which \((R_{G}^{2})_{LS} = 3R^{2}/5\), \(y(\bar{n}, \lambda, M)\) may be expressed as \(y_{p}(\bar{n}, \alpha)\), and calculated as a function of \(\bar{n}\) and \(\alpha = 2\pi R/\lambda\) (see Bohren and Huffman,\(^{13}\) p. 113; Kerker,\(^{21}\) p. 91; van de Hulst,\(^{22}\) p. 127). Consequently, for monodisperse spheres, Equation (30) applies

\[
(R_{G}^{2})_{LS} = \left( \frac{3}{5} y_{p}(\bar{n}, \alpha) R^{2} \right)
\]

(30)

where \(y_{p}(\bar{n}, \alpha)\) is the scattering per portion of the particle. Examples of \((R_{G}^{2})_{LS} = 3R^{2}/5\) are shown in Figure 2 over a range of \(\alpha\) and \(n\), showing the complex character of this function. Expansion of \(y_{p}(\bar{n}, \alpha)\) for \(\bar{n} \alpha \leq 1\) gives a result (van de Hulst,\(^{22}\) p. 45) that may be cast in the form, \(y_{p}(\bar{n}, \alpha) \approx p_{p}(\bar{n}) = (\bar{n}^{2} + 2(\bar{n}^{2} + 4)/(3(2\bar{n}^{2} + 3))\), where \(p_{p}(\bar{n})\) approaches unity as \(\bar{n}\) tends to unity, so that \((R_{G}^{2})_{LS} = 3R^{2}/5\) as \(\bar{n}\) tends to unity and \(\bar{n} \alpha \ll 1\), as expected in the RGD regime. It may be noted that even if \(\alpha \ll 1\), so that \(m_{p}(\bar{n}, \alpha) \approx 1\) and \(p_{p}(\bar{n}, \alpha) \approx p_{p}(\bar{n})\), \((R_{G}^{2})_{LS}\) tends to \(\bar{n}^{2}/10\) for \(\bar{n} \gg 1\) (but \(\bar{n} \alpha \leq 1\)). The dependence on \(\bar{n}\) for small \(\alpha\) is most clearly seen in Figure 2(a); the fit of this approximate relation is good for \(\alpha < 1\). Since \((R_{G}^{2})_{LS} = 3R^{2}/4\), independent of \(\bar{n}\), in the Fraunhofer scattering regime (\(\alpha \gg 1\) and \(\bar{n} \gg 1\)) discussed in the next.
section (see Kerker,\(^{(21)}\) p. 325), \(^{43,44}\) \(y_{\text{ph}}(\hat{n}, \alpha)\) tends to 5/4 in that limit; the values of \(\alpha\) used in Figure 2 are too small to exhibit such behavior. Similar expressions could be developed for other particles to which the Mie theory has been applied, e.g. stratified spheres and related structures mentioned in the preceding (see Bohren and Huffman,\(^{(13)}\) p. 475).\(^{(45,46)}\)

As may be seen in Figure 2, the transition from the behavior for \(\hat{n} \approx 1\) and \(\hat{n}\alpha \ll 1\) to that for \(\alpha \gg 1\), for any \(\hat{n}\), is complex, prohibiting an analytic representation of \((R_{\text{LS}}^2)_{\text{LS}}\) for a sample of unknown size distribution. Thus, although Equation (31)

\[
(R_{\text{LS}}^2)_{\text{LS}} = \left(\frac{3}{5} \sum_{\mu} w_\mu M_\mu y_{\text{ph}}(\hat{n}, \alpha_\mu) [m_{\text{ph}}(\hat{n}, \alpha_\mu)]^2 \right)^{2/3}
\]

holds for a collection of spheres of different size, but identical \(\hat{n}\), this cannot generally be reduced to an expression involving standard average molecular weights. In principle, assuming that both \((R_{\text{LS}}^2)_{\text{LS}}\) and \(M_{\text{LS}}\) can be determined (which may be difficult for large particles), one could compare these with values of \((R_{\text{LS}}^2)_{\text{LS}}\) and \(M_{\text{LS}}\) calculated with an assumed two-parameter distribution function of \(M\) as a means to characterize the size distribution, e.g. for spheres, using the Mie theory to compute \(y(\hat{n}, \lambda, M_\mu) = y_{\text{ph}}(\hat{n}, \alpha_\mu)\) and \(m(\hat{n}, \lambda, M_\mu) = m_{\text{ph}}(\hat{n}, \alpha_\mu)\). In essence, a similar strategy is adopted by methods that attempt to fit the scattering determined at two small scattering angles (see Kerker,\(^{(21)}\) p. 351).\(^{(44)}\) In addition, in principle, the dependence on \(\lambda\) embodied in the parameters \(\alpha_\mu\) provides a means of interpreting \((R_{\text{LS}}^2)_{\text{LS}}\) in terms of \(w_\mu\) from the variation of \((R_{\text{LS}}^2)_{\text{LS}}\) with \(\lambda\) using the Mie theory to compute \(y_{\text{ph}}(\hat{n}, \alpha_\mu)\) and \(m_{\text{ph}}(\hat{n}, \alpha_\mu)\), after accounting for any dispersion in the refractive indices of solute or solvent.

### 2.3.3 Anisotropic Solute

An estimate for \((R_{\text{LS}}^2)_{\text{LS}}\) may be obtained from the dependence of either \([K^c/R_{\text{LS}}(\theta, c)]^0\) or \([K^c/R_{\text{LS}}(\theta, c)]^0\) for the scattering from anisotropic solutes in the RGD regime. Thus, for a solute with identical scattering elements, expressions for semiflexible chains give Equations (32) and (33),\(^{(10,41,47–49)}\)

\[
P_{\text{VV}}(\theta, 0) = 1 + \left[ \frac{[J_{\text{VV}}(\delta)]_{\text{LS}}}{3} \right]_{\text{LS}} g^2
\]

\[
P_{\text{HH}}(\theta, 0) = 1 + \left[ \frac{[J_{\text{HH}}(\delta)]_{\text{LS}}}{7} \right]_{\text{LS}} g^2
\]

Expressions for \([J_{\text{VV}}(\delta)]_{\text{LS}}\) and \([J_{\text{HH}}(\delta)]_{\text{LS}}\) are available for semiflexible chains.\(^{(10)}\) In practice, the expression for rod-like chains (i.e. \(\alpha/L > 1\)) may be used as a first approximation for any \(\alpha/L\), since \([J_{\text{VV}}(\delta)]_{\text{LS}} \approx (R_{\text{LS}}^2)_{\text{LS}}\) and \([J_{\text{HH}}(\delta)]_{\text{LS}} \approx (\delta^2 R_{\text{LS}}^2)_{\text{LS}} \approx 0\) as \(\alpha/L\) becomes small and \(\delta\) tends to zero for flexible chains;\(^{(10)}\) see section 4, “Examples”.

### 2.4 Scattering at Arbitrary Angle and Infinite Dilution

#### 2.4.1 Isotropic Solute in the Rayleigh–Gans–Debye Regime

The angular dependence of the scattering over a wide angular range provides additional information on solute structure and dispersity, at least in principle. In practice, the effects of these two attributes may frustrate analysis, e.g. even in the preceding case for small scattering angle, the dependence of \((R_{\text{LS}}^2)_{\text{LS}}\) on average molecular weights depends on the solute structure, see Table 1. For an optically isotropic solute (averaged over all orientations) in the RGD approximation,\(^{(1,10,18)}\) Equations (34) and (35) apply

\[
P_{\text{VV}}(\theta, 0) = \frac{[R_{\text{LS}}(\theta, c)/K^c]^0}{M_{\text{LS}}^2 \psi_{\text{solvent}}^2}
\]

\[
P_{\text{VV}}(\theta, 0) = \sum_{\mu} w_\mu M_\mu^{-1} \sum_{ij} \psi_{ij} \psi_{ij} \mu_\mu \times ( \sin(q|r_{ij}|)/q|r_{ij}| ) M_{\text{LS}} \psi_{\text{solvent}}^2
\]

where each sum runs over the \(M/m\) scattering elements on a component, and the second form is written in the RGD approximation. Expansion of the factor in \(\langle \cdots \rangle\) brackets yields the relation in terms of \((R_{\text{LS}}^2)_{\text{LS}}\) given above. Equations (36) and (37) apply to optically identical scattering elements with molar mass \(m\),

\[
P_{\text{VV}}(\theta, 0) = \frac{\sum_{\mu} w_\mu M_\mu [P_{\text{VV}}(\theta, 0)]_{\mu}}{M_w}
\]

\[
[P_{\text{VV}}(\theta, 0)]_{\mu} = \frac{m}{M} \sum_{ij} \frac{( \sin(q|r_{ij}|)/q|r_{ij}| )_{\mu}}{\mu}
\]
a convenient approximation; inspection shows that it is not usually a good approximation unless $R_G^2q^2$ is small, providing the best fit for spheres among the examples in Figure 3. Given the availability of computational equipment, it is usually not necessary to resort to tabulated numerical values of $P_{V_v}(\theta, 0)$ for scatterers in the RGD approximation; an extensive compilation of formulae for $P_{V_v}(\theta, 0)$ for a variety of macromolecular and particle shapes to supplement the entries in Table 2 may be found in Kerker (p. 482).\(^{(21)}\) In most cases, $P_{V_v}(\theta, 0)$ may be expressed in terms of $q$ in the RGD approximation, but with some structures, $P_{V_v}(\theta, 0)$ depends explicitly on $\theta$, as well as on $q$, e.g. for a rod-like chain (see Table 2).

In some models, the summations in $P_{V_v}(\theta, 0)$ may be completed in terms of standard molecular-weight averages ($M_n$, etc.) without specification of a particular expression for the distribution $w_{\mu}$. For example, for random-flight linear chains (e.g. at the Flory $\theta$ temperature), using $P_{V_v}(\theta, 0)$ in Table 2,\(^{(1,42)}\) Equation (38)

$$P_{V_v}(\theta, 0) = \frac{2M_n}{M_wu_n^2} u_n - 1 + \sum_{\mu} w_{\mu} \left( \frac{M_n}{M_\mu} \right) \times \exp \left( -u_n \frac{M_\mu}{M_n} \right)$$

(38)

where $u_n = (R_G^2/M_n)q^2$, with $R_G^2/M$ a constant for this model. Further analysis requires an expression for $w_{\mu}$, and this would be the normal situation with most forms for $P_{V_v}(\theta, 0)$. For example, in this case, using the Schulz–Zimm (two-parameter exponential) distribution function,\(^{(1,31,42)}\) the remaining sum is equal to $(1 + u_n/h)^{-h}$, where $h^{-1} = (M_n/M_w) - 1$. For a most-probable distribution of molecular weight ($h = 1$), this reduces the expression to a simple form linear in $q^2$, Equation (39):\(^{(1,31,42)}\)

$$P_{V_v}(\theta, 0) = 1 + \frac{(R_G^2)_{LS}q^2}{3}$$

(39)

exactly, with $(R_G^2)_{LS} \propto M$, for this model for a linear polymer.\(^{(42,50)}\) The same result obtains for a randomly branched flexible chain polymer.\(^{(12)}\) An expression for $P_{V_v}(\theta, 0)$ for rod-like chains with the same distribution of molecular weight is available in the form of a series to be summed over $h - 1$ terms.\(^{(10)}\) Examples of $P_{V_v}(\theta, 0)^{-1}$ computed for the random-flight linear chain and the sphere models using the Schulz–Zimm distribution function are shown in Figure 4.

The expression for $P_{V_v}(\theta, 0)$ given in Table 2 for linear flexible coil chains assumes random-flight chain statistics, and therefore is not strictly applicable to polymer chains in so-called “good solvents” (i.e. solvents for which $A_2 \gg 0$), for which excluded volume effects introduce a nonlinear dependence of $|r_j|$ on the separation of scattering elements $i$ and $j$, resulting in a dependence of $R^2_G/L$ on $L$ (see Yamakawa,\(^{(20)}\) p. 302).\(^{(51)}\) In practice, the expression given in Table 2 may usually be used in good solvents for the range of $(R_G^2)_{LS}q^2$ of usual interest, provided that the observed $(R_G^2)_{LS}$ is used, as opposed to the value of $(R_G^2)_{LS} = \dot{\alpha}M_c/3$ obtaining under Flory $\theta$ conditions ($A_2 = 0$) called for by the model. Treatments attempting to include excluded volume effects by calculation of $P_{V_v}(\theta, 0)$ using a model for which $|r_{ij}| = |i - j|^{1+\beta}$, with $0 \leq \beta \leq 1$, have been developed as an alternative.\(^{(18,52)}\) Similarly, although $[P_{V_v}(\theta, 0)]_{BR}$ has been computed for a variety of branch chain configurations,\(^{(12,53,54)}\) the expression $[P_{V_v}(\theta, 0)]_{LIN}$ for linear flexible chains provides a first approximation to $[P_{V_v}(\theta, 0)]_{BR}$, provided $(R_G^2)_{BR}$ observed for the branched chain is used in place of $(R_G^2)_{LIN}$ appearing in $[P_{V_v}(\theta, 0)]_{LIN}$.
of this are shown in Figure 5 for a range of comb-shaped branched chains with different fractions \( \varphi \) of monomers in the backbone and different numbers of branches \( f \) per molecule (e.g. \( \varphi \) is zero and unity for linear and star-shaped structures, respectively); substantial deviations are noted between the approximation and the expected behavior for \((R_G^2)_{BR} > 3\). It may be noted that the ratio \( g = (R_G^2)_{BR}/(R_G^2)_{LIN}\) of the \( R_G^2\) for branched and linear chains of the same \( M \) is frequently used in discussions of branched chains, but that is a sufficient descriptor only for self-similar structures, such as star-shaped branched chains. For example, comb-shaped branched chains with different \( \varphi \) and \( f \) may have the same \( g \), as exemplified by Equation (40)

\[
g \approx \varphi + \frac{(1 - \varphi)^{1/3}(3f - 2)}{f^2}
\]

which provides a useful approximation for this model.\(^{53}\)

A similar form applies for randomly branched polymers,\(^{55}\) with \( g_w \approx \varphi_w \), where \( \varphi_w = M_w \) for the longest linear chain in the branched structure divided by the total molecular weight, and \( g_w = (g_w w_\mu M_\mu) / M_w \). See further discussion in section 4.

In the limit of very large \((R_G^2)_{BR}q^2\), for thread-like chains in the RGD approximation\(^{10,18,54}\), Equation (41) applies for a solute with \((R_G^2)_{BR} = r M_\mu^2 \) (e.g. see Table 1).

\[
\lim_{(R_G^2)_{BR}q^2 \gg 1} [P_{V_\varphi}(\theta, 0)]_{\mu}^{-1} \approx s_\mu (r_{12} q^2)^{1/2} + i_\mu + O(q^{-2})
\]

(41)

where \( i_\mu \) and \( s_\mu \) are numbers that depend on the solute structure. Thus, for a rod-like solute \((\epsilon = 2\) and \( r = (L/M)^2/12\), with \( L \) the chain contour length,\(^{10,18,56}\) Equations 42 and 43)

\[
\lim_{(R_G^2)_{BR}q^2 \gg 1} [P_{V_\varphi}(\theta, 0)]_{\mu}^{-1} \approx \frac{L_{\mu}}{\pi} q + \left( \frac{2}{\pi^2} \right) + \cdots
\]

(42)

\[
\lim_{(R_G^2)_{BR}q^2 \gg 1} [P_{V_\varphi}(\theta, 0)]_{\mu}^{-1} \approx \frac{L}{\pi M} M_\mu q + \cdots
\]

(43)

showing that data on \( R_{V_\varphi}(\theta, 0) \) in this limit will provide the length per unit mass, but not the molecular weight; this situation may be realized with certain large rod-like structures.\(^{56}\) For linear or branched flexible chain polymers \((\epsilon = 1\) and \( r = g a L/3M\), with \( g \) the ratio of \( R_G^2\) for branched and linear chains with the same \( M\).\(^{10,18,54}\) Equations 44 and 45)
and small principle, investigation of the limiting behavior at large chain structure for branched chains. Consequently, in where $C$ chains for which $C$ linear flexible chain polymers (or for branched flexible experiments with flexible chain macromolecules, but it is behavior at large $q$ is seldom observed in light-scattering in these asymptotic expressions for large $(R_Q^2)_{LS}$. A related behavior obtains with spheres, in which the value of $P_{Vv}(\theta, 0)$ for successive maxima at large $qR$ decay as $(qR)^{-4}$ in the so-called Porod regime (see Kerker,\textsuperscript{(21)} p. 471; Guinier and Fournet,\textsuperscript{(24)} p. 17).\textsuperscript{(57,58)}

For a solute monodisperse in molecular weight, but comprising two types of scattering elements,\textsuperscript{(10,36,37)} Equations (46) and (47) apply

\begin{equation}
P_{Vv}(\theta, 0) = x[P_{Vv}(\theta, 0)]_A + (1 - x)[P_{Vv}(\theta, 0)]_B + x(1 - x)[Q_{Vv}(\theta, 0)]_{AB}
\end{equation}

\begin{equation}
[Q_{Vv}(\theta, 0)]_{AB} = 2[P_{Vv}(\theta, 0)]_{AB} - \{[P_{Vv}(\theta, 0)]_A + [P_{Vv}(\theta, 0)]_B\}
\end{equation}

where $x = w_A\Psi_A/w_{\text{solute}}$ as above, and $\Psi_{\text{solute}} \neq 0$. Here, $[P_{Vv}(\theta, 0)]_A$ and $[P_{Vv}(\theta, 0)]_B$ are calculated by the

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Figure_4}
\caption{Examples of $P_{Vv}(\theta, 0)^{-1}$ versus $q^2(R_Q^2)_{LS}$ for model structures with a weight distribution given by the two-parameter Zimm–Schulz distribution function, with $h = 1/[(M_w/M_n) - 1]$ as per the discussion in the text, for random-flight linear chains (a) and spheres (b), for the indicated values of $h$, with $h$ decreasing from top to bottom in each set of curves (the uppermost curve for the monodisperse case is bold in each set). The dashed line in (b) is the initial tangent.}
\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Figure_5}
\caption{Examples of $[P_{Vv}(\theta, 0)]_{BR}$ versus $q^2R_Q^2$ for comb-shaped branched chain polymers divided by $[P_{Vv}(\theta, 0)]_{LIN}$ for linear chains with the same $R_Q^2$ (not the same molecular weight). The number of branches is indicated, along with the fraction $\phi$ of mass in the backbone of the branched chain. (From Casassa and Berry,\textsuperscript{(53)})}
\end{figure}

\begin{equation}
\lim_{(R_Q^2)_{LS} \to 1} P_{Vv}(\theta, 0)^{-1} \approx \frac{rM_nq^2}{2} + \left(\frac{M_w}{M_n}\right) C + \cdots
\end{equation}

\begin{equation}
\approx \left(\frac{M_n}{M_G}\right) (R_Q^2)_{LS} q^2 \frac{C + \cdots}{2}
\end{equation}

where $C$ is 1/2 for linear chains and dependent on chain structure for branched chains. Consequently, in principle, investigation of the limiting behavior at large and small $q$ can provide values for $M_n$, $M_w$ and $M_G$ for linear flexible chain polymers (or for branched flexible chains for which $C$ is known). In practice, the limiting behavior at large $q$ is seldom observed in light-scattering experiments with flexible chain macromolecules, but it is possible to observe such behavior with low-angle X-ray or neutron scattering – it may, however, be difficult to observe the limiting behavior for large and small $q$ in the same experimental arrangement. Moreover, short-scale chain features not included in the models used to compute $P_{Vv}(\theta, 0)$ will introduce behavior not included in these asymptotic expressions for large $(R_Q^2)_{LS}$. A related behavior obtains with spheres, in which the value of $P_{Vv}(\theta, 0)$ for successive maxima at large $qR$ decay as $(qR)^{-4}$ in the so-called Porod regime (see Kerker,\textsuperscript{(21)} p. 471; Guinier and Fournet,\textsuperscript{(24)} p. 17).\textsuperscript{(57,58)}
expression given above, and \([P_{Vv}(\theta, 0)]_{AB}\) by a variation of this expression with one sum each over scattering elements of type A and B. The expressions for \(P_{Vv}(\theta, 0)\) in Table 2 apply for \(P\) chains.

Examples are available for random-flight linear elements of type A coated by a shell with outer radius \(R_{B}\) and scattering elements of type B. The expressions for \(P_{Vv}(\theta, 0)\), expansion of \([Q_{Vv}(\theta, 0)]_{AB}\), and \([P_{Vv}(\theta, 0)]_{AB}\) must be computed for each case. Expansion of \([Q_{Vv}(\theta, 0)]_{AB}\) gives the leading term \(\Delta_{AB}^{2}q^{2}/3\), with \(\Delta_{AB}^{2}\) as defined above, i.e., \([Q_{Vv}(0, 0)]_{AB}\) = 0. Examples are available for random-flight linear chains.\(^{36}\) Inspection shows that the initial tangent \(\partial[P_{Vv}(\theta, 0)]_{AB}^{-1}/\partial q^{2}\) may be negative, zero, or positive, reflecting the possibility mentioned above that \((R_{G})_{LS}\) may be positive, zero, or negative, respectively, for such a solute. For a sphere with radius \(R_{A}\) and scattering elements of type A coated by a shell with outer radius \(R_{B} > R_{A}\) and scattering elements of type B (Kerker,\(^{21}\) p. 419) (Equation 48)

\[
P_{Vv}(\theta, 0) = \left( x[P_{Vv}(\theta, 0)]_{B}^{1/2} + (1 - x) \right) \times \frac{R_{B}^{2}[P_{Vv}(\theta, 0)]_{B}^{1/2} - R_{A}^{2}[P_{Vv}(\theta, 0)]_{A}^{1/2}}{R_{B}^{2} - R_{A}^{2}}
\]

where the expressions for \([P_{Vv}(\theta, 0)]_{B}\) and \([P_{Vv}(\theta, 0)]_{A}\) are the functions for spheres with radii \(R_{B}\) and \(R_{A}\), respectively (given in Table 2). This expression reduces to \(P_{Vv}(\theta, 0)\) for a shell of thickness \(\Delta = R_{B} - R_{A}\) filled with the solvent for \(x = 0\), or to \(P_{Vv}(\theta, 0)\) for a sphere of radius \(R_{A}\) if \(x = 1\). In using this relation, it must be remembered that \(w_{A} \propto \rho_{A}R_{A}^{3}\) and \(w_{B} = 1 - w_{A} \propto \rho_{B}(R_{B}^{3} - R_{A}^{3})\). If \(\psi_{solute} = 0\), then \([R_{Vv}(0, c)/Kc]^{0}\) = 0, but \([R_{Vv}(\theta, c)/Kc]^{0}\) for \(\theta > 0\) may be computed using Equation (48) with \(x = 0\) and \(1 - x\) replaced by \(w_{A}\psi_{A}\) and \(w_{B}\psi_{B}\), respectively. The result will exhibit a series of maxima for \(\theta > 0\), with a superficial similarity to \(R_{Vv}(\theta, c)\) observed with charged spheres, arising from interactions among the scatterers, see section 4.

2.4.2 Isotropic Solute Beyond the Rayleigh–Gans–Debye Regime

Although the accuracy of the RGD approximation varies with \(\theta\) and \(\bar{n}\), deviations from the Mie theory are usually small if \(\alpha(\bar{n} - 1) < 0.25\) (but this depends on \(\theta\) and both \(\alpha\) and \(\bar{n}\) individually in detail) (Kerker,\(^{21}\) p. 427; van de Hulst,\(^{22}\) p. 131). With the RGD approximation, \(P_{\text{ls}}(\theta, 0) = P_{Vv}(\theta, 0)\cos^{2}(\theta)\), but this relation does not usually hold if the phase shift is not small. The Mie theory provides expressions for \(P_{Vv}(\theta, 0)\), \(P_{\text{ls}}(\theta, 0)\), and \(P_{\text{ls}}(\theta, 0)\) for optically isotropic nonabsorbing spheres as the square of sums over functions of \(\theta\) and the relevant refractive indices (see Bohren and Huffman,\(^{13}\) p. 113; Kerker,\(^{21}\) p. 97; van de Hulst,\(^{22}\) p. 131).\(^{8}\) Examples shown in Figure 6 give \(P_{Vv}(\theta, 0)\) as a function of \(q^{2}(R_{G})_{\text{LS}}\) for a particular value of \(\alpha = 2\pi R/\lambda\), over a range of \(\bar{n}\), with

![Figure 6](image_url)

**Figure 6** Examples of \(\log[P_{Vv}(\theta, 0)]\) versus \(q^{2}(R_{G})_{\text{LS}}\) for spheres with size parameter \(\alpha = 2\pi R/\lambda = 4\) for the indicated values of the relative refractive index \(\bar{n}\). The angular range is 0 to 180 degrees in all cases except for \(\bar{n} = 2.0\). The RGD limiting case for very small \(\bar{n} - 1\) is given by the bold dashed curve. The dashed line gives the initial tangent. Values of \((R_{G})_{\text{LS}}/(3R_{G}^{2}/5)\) may be seen for this \(\alpha\) in Figure 2.
\( \lambda = \lambda_0 / n_{\text{medium}} \) (e.g. the \( \alpha \) value chosen in the example would correspond to aqueous suspensions of spheres with \( R \approx 300 \text{ nm} \), with \( \lambda_0 = 633 \text{ nm} \)). The extreme dependence on \( \tilde{n} \) may be observed, emphasizing the need to know this parameter accurately in this regime, and showing that it would be impossible to analyze the size distribution for an ensemble of spheres with heterogeneity of both \( \tilde{n} \) and \( R \). The data in Figure 6 are shown as \( \log [P_{\mathrm{Vs}}(\theta, 0)] \) versus \( q^2(R_{\text{c}}^2 - 1)_{\mathrm{LS}} \) to emphasize the correspondence at small \( q \), but the systematic variation of \( q^2(R_{\text{c}}^2 - 1)_{\mathrm{LS}} \) for the first minimum in \( P_{\mathrm{Vs}}(\theta, 0) \) with \( \tilde{n} \). In this format, the minima in \( P_{\mathrm{Vs}}(\theta, 0) \) tend to occur near the values of \( q^2(R_{\text{c}}^2 - 1)_{\mathrm{LS}} \) for the minima in the RGD approximation. Similar behavior may be observed for other values of \( \alpha \), including \( \alpha \) large enough to be in the Fraunhofer diffraction limit discussed below.

Numerical methods to compute \( P_{\mathrm{Vs}}(\theta, 0) \) are available for a number of particle shapes (see Bohren and Huffman). Fortunately, electronic computation at the desktop can facilitate the use of these, although extensive tables of the functions appearing in the Mie theory for the scattering from spherical particles are available (Kerker, p. 78) (the functions reported herein were calculated using a MathCad file, kindly provided by D. C. Prieve, of the Department of Chemical Engineering of Carnegie Mellon University, with the number of terms in the relevant sums terminated at the next integer larger than \( \alpha + 4\pi^2/3 + 4 \) (slightly larger than an expression advocated in the literature (see Bohren and Huffman, p. 477) for accessible \( \alpha \); data in published tables are useful to confirm the methods used in such calculations). Comparable expressions are available in the Mie approximation for shells, stratified spheres, and examples with a continuous radially symmetric variation (see Bohren and Huffman, p. 475; Kerker, p. 189; cylinders and ellipsoids (Kerker, p. 255)). The application of these for polydisperse systems requires the use of Equation (36) to compute the observable \( P_{\mathrm{Vs}}(\theta, 0) \), usually by a numerical analysis.

For both \( \tilde{n} \gg 1 \) and phase shift magnitude \( \alpha(\tilde{n} - 1) > 10 \), the angular dependence reduces to a regime termed the Fraunhofer diffraction limit (see Bohren and Huffman, p. 482; Kerker, p. 159; van de Hulst, p. 108). In that regime, the angular dependence is independent of \( \tilde{n} \), and the same for absorbing or nonabsorbing particles. For example, for a spherical solute, the angular dependence of the scattering (for a monodisperse solute at infinite dilution) is that for Fraunhofer diffraction from a circular aperture, Equation (49)

\[
\lim_{R/\alpha \gg 1} P_{\mathrm{Vs}}(\theta, 0) = \left( \frac{2 J_1(\alpha \sin(\theta))}{\alpha \sin(\theta)} \right)^2 \tag{49}
\]

where \( \alpha = 2\pi R/\lambda, J_1(\cdots) \) is the Bessel function of the first kind and first order. For a polydisperse spherical solute in this regime, Equation (50)

\[
\lim_{R/\alpha \gg 1} \frac{R_{\text{c}}(\theta, 0)}{c} \propto \sum_{\mu} n_{\mu} a_{\mu}^6 \frac{2 J_1(\alpha_{\mu} \sin(\theta))}{a_{\mu}^2 \sin(\theta)} \tag{50}
\]

where \( n_{\mu} \) is the number fraction of spheres with radius \( R_{\mu} \). As discussed below, the simplicity of this result can be exploited in methods to determine the size distribution from \( \{R_{\text{c}}(\theta, c)\} \). Similar results obtain for other particle shapes. For example, for cylinders with length \( L_{\text{cyl}} \) and radius \( R \), in the same limit, and with \( L_{\text{cyl}} \gg R \gg \lambda \) (van de Hulst, p. 108), Equation (51)

\[
\lim_{R/\alpha \gg 1} P_{\mathrm{Vs}}(\theta, 0) = \frac{\sin^2(\alpha \theta)}{(\alpha \theta)^2} \tag{51}
\]

Since the patterns of the extrema are similar for these two functions, it would not be possible to differentiate between solutes with these two shapes from the scattering in this limit. Nor can the expression for cylinders with \( L_{\text{cyl}}/R \gg 1 \) be used to determine the distribution of cylinder lengths.

It has been observed that in the regime for which Mie scattering theory applies for optically isotropic spheres, the angular dependence for small angles may be approximated by the expression for the Fraunhofer regime given above, even if \( R \) is not much larger than \( \lambda \) (see Kerker, p. 351). Although the discussion of \( (R_{\text{c}}^2 - 1)_{\mathrm{LS}} \) in the preceding shows that this cannot be accurate for small angles (and is inaccurate for the RGD regime), it may, nevertheless, be a useful approximation over most of the regime for which the Mie theory is needed, offering a substantial simplification in the analysis of the size distribution in such cases.

If \( \alpha \gg 1 \), but \( \tilde{n} \approx 1 \) (e.g. for a particle immersed in a solvent with closely matching refractive index), so that the phase shift \( \alpha(\tilde{n} - 1) \) is small, the angular dependence differs considerably from that for Fraunhofer diffraction for larger \( \theta \), in a regime called anomalous diffraction (see van de Hulst, p. 183) giving what has been characterized as “a set of queer scattering diagrams” (van de Hulst, p. 183). So-called anomalous scattering approximations to the Mie theory have been obtained in this regime for spheres (van de Hulst, p. 172), reported to be accurate for computation of \( P_{\mathrm{Vs}}(\theta, 0) \) in the regime \( \tilde{n} - 1 < 0.1, 2\alpha(\tilde{n} - 1) < 0.1, \) and \( \alpha > 1 \). Use of the Fraunhofer diffraction approximation would, for example, give an erroneous estimate of the size distribution, see section 4. It is reported that depolarized scattering may result from isotropic spheres in this regime. The preceding discussion has been limited to scattering with polarization of the incident and scattered beams either perpendicular or parallel to the scattering plane, the plane defined by incident and scattered beams. A more general notation is needed to discuss the anisotropic scattering for spheres since \( P_{\text{Vs}}(\theta, 0) \) as
defined above is zero for isotropic spheres. In a more
general description, the scattering plane may contain
the incident beam and be at an azimuthal angle ϕ relative
to the polarization of the incident light for vertically
polarized light. Thus, ϕ = π/2 for the scattering plane
considered thus far. An alternative nomenclature lets Vv
and Hv indicate parallel and crossed polars, respectively,
as in the preceding, but supplements the description
by adding the azimuthal angle, e.g. $P_{1b}(ϕ, ϕ, c)$, so
that $P_{1b}(ϕ, 0)$, $P_{Vv}(ϕ, 0)$, and $P_{Hv}(ϕ, 0)$ discussed above
become $P_{1b}(ϕ, π/2, 0)$, $P_{Vv}(ϕ, π/2, 0)$, and $P_{Vv}(ϕ, 0, 0)$,
respectively. It has long been known that $P_{1b}(ϕ, π/4, 0)$ is
not zero for optically anisotropic spheres (see below), with
a first maximum in $P_{1b}(ϕ, π/4, 0)$ occurring at an angle
ϕ may be used to estimate the size of the sphere,
see below.(5) Calculations in the RGD approximation
and using the Mie theory reveal that a similar maximum
occurs with optically isotropic spheres in the anomalous
diffraction regime,(71) in agreement with observations on
spheres thought to be optically isotropic.(70)

2.4.3 Anisotropic Solute

With the exception of semiflexible chains with rela-
tively large a/L, anisotropic scattering may normally
be neglected in the excess scattering for polymer solu-
tions (note that many solvents will exhibit anisotropic
scattering, which must be accurately determined to study
the excess anisotropic scattering due to the solute). The
functions $P_{1b}(ϕ, 0)$ and $P_{Vv}(ϕ, 0)$ for rod-like chains
are given in Table 2, and are discussed in more detail below
in an example, along with the anisotropic scattering from
particles.

Expressions for $P_{Vv}(ϕ, 0)$ and $P_{Hv}(ϕ, 0)$ for optically
anisotropic rod-like molecules in the RGD regime are
given in Table 2, and discussed below in section 4. The
functions $P_{1b}(ϕ, ϕ, 0)$ and $P_{Vv}(ϕ, ϕ, 0)$ defined above have
been computed for optically anisotropic spheres and other
particle shapes.(5,26–72) A principal result for anisotropic
spheres is that $P_{1b}(ϕ, π/4, 0)$ exhibits extrema as a
function of qR for monodisperse spheres (see Kerker,(21)
p. 674).(5,45,70,71–76) see section 4.

2.5 The Size Distribution from Scattering Data at
Infinite Dilution

In the preceding, the characterization of the size distri-
bution is through averages of M and $R^2_G$. Thus, with
a model relating $R^2_G$ to M, the different averages in $M_{LS}$
and $(R^2_G)_{LS}$ can permit an estimate of the breadth of the
size distribution. Two principal methods are used to esti-
mate more detailed information on the size distribution:
(i) comparison of experimental $P_{Vv}(ϕ, 0)$ with that calcu-
lated with an assumed distribution of M (or some other
equivalent size parameter, such as R for spheres), and
(ii) inversion of $P_{Vv}(ϕ, 0)$ to obtain the size distribution
function. Neither is entirely satisfactory, each with its own
set of limitations. In either case, it is necessary to have a
model for $P_{Vv}(ϕ, 0)$, and to assume that the model applies
to all scatterers in the system. Further, as a practical
matter, it must be assumed that all components are iden-
tical in composition. In practice, data on $R_{Vv}(ϕ, c)/Kc$
are often used to estimate a size distribution, rather
than $P_{Vv}(ϕ, 0)$, or even $[R_{Vv}(ϕ, c)/Kc]^2$. As discussed in
the next section, this practice may introduce distortions
to the size estimate unless $2(A_2)_{LS}M_{wC}$ ≪ 1. Multi-
ple scattering is an additional practical issue sometimes
encountered, especially in the scattering from dispersions
of particles for which $R_{Vv}(ϕ, c)/Kc$ is not extrapolated
to infinite dilution. Some schemes have been introduced to
account for this effect, especially in the scattering from
large spheres,(79–83) but in general it should be avoided by
reducing the solute concentration, though this can have
a deleterious effect on the estimate of the population of
very small scattering components in the presence of large
particles.

In the first method, a model is used to compute
$P_{Vv}(ϕ, 0)$ for comparison with the experimental data,
based on an (assumed) solute structure and an assumed
two or three parameter molecular-weight distribution
function, e.g. one of the several functions given by
Berry(42) with parameters $M_w/M_n$, $M_z/M_w$, etc. or
alternatively, for spheres, these functions are expressed
as a distribution in R with parameters $R_m/R_n$, $R_z/R_w$, etc.
Estimates of $M_w$ and $(R^2_G)_{LS}$ may be used to guide
estimation of the parameters in the distribution function
if these are available; in some cases, for a solute with
very large $M_w$ it may not be possible to obtain the
reliable extrapolation to zero scattering angle needed
to estimate these parameters. For example, experimental
data on $P_{Vv}(ϕ, 0)$ for linear flexible chains or spheres
(in the RGD regime) could be compared with Figure 4,
calculated using the two-parameter exponential function
mentioned above, to estimate the molecular-weight
dispersion. Comparison with $P_{Vv}(ϕ, 0)$ for semiflexible
chains provides an example of the ambiguity in matching
experimental and calculated $P_{Vv}(ϕ, 0)$ unless a reliable
model is available. A similar situation obtains with
particles, e.g. deviations from spherical symmetry will
result in distortions of the scattering function similar to
those caused by a distribution of size in spheres.

There is a long history of attempts to implement a direct
inversion of $P_{Vv}(ϕ, 0)$ (or $[R_{Vv}(ϕ, c)/c]^2$) for polysize
scatterers (usually particles with spherical symmetry)
to obtain a size distribution of the scattering species,
much of it demonstrating the difficulty of obtaining
reliable results. Present-day treatments are facilitated by
the availability of computational facilities at the desk.
top to implement the computations, with almost all applications being to the size distribution of particles owing to the nature and limited accessible span of $P_{V_n}(\theta, 0)$ for macromolecules. Two principal methods are used, depending on the size of the particles: numerical inversion of the data via iterative techniques, and evaluation of an integral expression based on Fraunhofer diffraction for particles with dimensions much greater than the wavelength, $\theta \gg 1$. The numerical inversions required are similar in kind to those applied to estimate size distributions from dynamic light scattering data, which involves a similar inversion relation, with similar limitations. For example, inversion is frequently attempted for the normalized electric-field correlation function $g_{LS}^{(1)}(\tau; \theta, c)$ of dynamic light scattering, given by
\[ g_{LS}^{(1)}(\tau; \theta, c) = \sum_{\mu} w_{\mu} M_{\mu} [P_{V_n}(\theta, 0)]_\mu \frac{\exp[-\tau g_{\mu}(q)]}{M_n P_{V_n}(\theta, 0)} \] (Equation (52) (see also Chu, p. 243))
in the limit of infinite dilution, with $g_{\mu}(q)$ the relaxation rate of the component $\mu$. The similarity of this to the expression, Equation (53)
\[ P_{V_n}(\theta, 0) = \frac{\sum_{\mu} w_{\mu} M_{\mu} [P_{V_n}(\theta, 0)]_\mu}{M_n} \] (Equation (53))
of interest here is evident, with a principal distinction being that the range of $\tau$ may be made much larger than the corresponding range in $\theta$ (or $q$), to the accuracy of data in the inversion. On the other hand, data acquisition is usually more time-consuming in dynamic scattering. In some cases, it is convenient to replace $w_{\mu}$ by the number fraction $n_{\mu}$ of species with molecular weight $M_{\mu}$, with $w_{\mu} = n_{\mu} M_{\mu}/M_n$, but in either case, implementation of an inversion protocol requires a relation between $M_n$ and a size parameter appearing in $[P_{V_n}(\theta, 0)]_\mu$, e.g. as in Table 1. Furthermore, the inversions are ill-posed for both static and dynamic scattering functions and constraints must be imposed to obtain a stable inversion.

It may be noted that expressions of this kind have been used for many years in the analysis of X-ray scattering data on particles, often with $P_{V_n}(\theta, 0) \approx \exp(-R_G^2 q^2/3)$, along with a model to express $R_G^2$ in terms of $M$, e.g. $R_G^2 \propto M^{2/3}$ for a spherical particle (Guinier and Fournet, p. 151). The several difficulties that hamper the determination of the molecular-weight (or size) distribution by an inversion of $P_{V_n}(\theta, 0)$ include:

1. the ill-posed character of the inversion
2. the need to have a theoretical $P_{V_n}(\theta, 0)$
3. noise in the data
4. the physical range of $\theta$, and hence the limited accessible $q$
5. uncertainty in the relative refractive index $\bar{n} = n_{\text{solute}}/n_{\text{medium}}$
6. the effects of solute aggregation
7. the effects of multiple scattering.

Various procedures have been investigated to effect the inversion, including versions of the methods used to invert dynamic scattering data, such as the constrained regularization method called CONTIN, as well as other methods (see Chu, p. 277). As discussed above, the RGD approximation is generally valid for a nonabsorbing solute if the phase shift within the molecule or particle is small enough. Although this is generally met for a polymeric solute, a direct inversion of $P_{V_n}(\theta, 0)$ is seldom of interest in such cases owing to the limited range of $(R_G^2)_{\text{LS}} q^2$ typically accessible for the scattering for a polymeric solute, as well as the limitations due to noise in the experimental data, e.g. see the comments above on the difficulties of obtaining reliable behavior at large $q$. By contrast, with larger particulate solutes, $P_{V_n}(\theta, 0)$ may typically cover a wider range, and perhaps exhibit maxima and minima, for the accessible range of $(R_G^2)_{\text{LS}} q^2$. As discussed above, the RGD approximation may be used for a range of particle sizes, but in such cases, the range of $(R_G^2)_{\text{LS}} q^2$ may not be large, in which case the inversion may not be accurate, depending on the particle shape. For larger phase shift, $M_n$ must be replaced by $M_{\text{LS}}$, and the Mie theory may be used for spheres to compute the $[P_{V_n}(\theta, 0)]_\mu$, needed in the inversion for particles with spherical symmetry, albeit with an increase in the computational time required. Similar treatments are available for other shapes, including spherical shells (Bohren and Huffman, p. 109), spheroids of revolution and rods, but it is not possible to permit both the particle shape and the size distribution to be unknowns in an inversion of the scattering from a polydisperse sample. Inversions in this regime may be reasonably stable and accurate, but usually require an accurate estimate of $n_{\text{solute}}/n_{\text{medium}}$, along with the attention of one skilled in the art to avoid erroneous results, see section 4.

The expression for $[R_{\text{LS}}(\theta, c)/c]^0$ given above in the Fraunhofer limit, with $R \gg \lambda$, may be used to obtain an integral equation for the number fraction of spheres with a given radius, eliminating the interactive methods described above. Experimental instruments to acquire data for this purpose differ in their design and in the form of the integral expression used. A systematic, consistent analysis of these given by Koo and Hirsleman is discussed below in section 4.
2.6 Extrapolation to Infinite Dilution

All of the preceding has presumed that $R_{\infty}(\theta, c)/c$ and $R_{\infty}(\theta, c)/c$ may be reliably extrapolated to infinite dilution. For dilute solutions, as discussed in section 2.1, $R_{\infty}(\theta, c)/c$ may be expressed in the form of Equation (54)

$$\frac{R_{\infty}(\theta, c)}{KMC} = \gamma_{\infty}(\theta, c) = \frac{P_{\infty}(\theta, c)}{[1 + c\Gamma_{\infty}(c)P_{\infty}(\theta, c)H_{\infty}(\theta, c)]}$$

(54)

where $K = K^{\gamma_{\text{solute}}^2}$, with a similar expression for $R_{\infty}(\theta, c)/c$. The function $H_{\infty}(\theta, c)$, which is usually close to unity, is discussed below, as is the possible dependence of $P_{\infty}(\theta, c)$ on $c$, the latter principally reflecting changes in the mean-square radius of gyration with $c$. Since $P_{\infty}(\theta, c)/KMC \approx 1$ for $c^2(R^2_{G\infty})_s$ $\gg$ 1, one can anticipate that $R_{\infty}(\theta, c)/KMC \approx P_{\infty}(\theta, c)$, for any concentration in that limit. The range of $(R^2_G)_s$ $\gamma^2$ required to observe this convergence depends strongly on the solute structure.

For $\theta = 0$, $P_{\infty}(0, c) = H_{\infty}(0, c) = 1$, and for dilute solutions, a virial expansion may usually be used to represent $\Gamma_{\infty}(c)$, with the result (see Yamakawa, p. 186)\(^{4,10,31}\) (Equation 55)

$$\frac{Kc}{R_{\infty}(0, c)} = M_{LS}^{-1/2}(1 + 2(A_2)_{LS}M_{LS}c + 3(A_2)_{LS}M_{LS}P^2 + \cdots)$$

(55)

For systems with large $A_2$, “good solvents”, the term in $c^2$ may introduce appreciable curvature, motivating the use of the relation\(^{4,10}\) Equation (56)

$$\frac{Kc}{R_{\infty}(0, c)} = M_{LS}^{-1/2}[1 + (A_2)_{LS}M_{LS}c + \alpha_3((A_2)_{LS}M_{LS})^2 + \cdots]$$

(56)

where $\alpha_3 = (3(A_2)_{LS}M_{LS}/(A_2)_{LS}M_{LS}^2 - 1)/2$; $\alpha_3$ tends to be small for large systems with $A_2$, making the extrapolation more nearly linear with larger $(A_2)_{LS}M_{LS}$ than with the first form. Possible exceptions to the behavior given by these relations may obtain if the solute is charged and the solvent is of very low ionic strength.\(^{16,32}\)

Although the behavior for more concentrated solutions is outside the scope of this article, it may be noted that expressions are available for moderately concentrated solutions, both in good solvents, and under Flory $\theta$ conditions, for which $A_2$, but not $A_3$, is zero. In the latter case, the expression given above terminated at the term in $c^2$ provides a good fit to the data, whereas with good solvents, power-law expressions in $A_2MC$ may be used to replace the factor in $[\cdots]$ in Equation (55)\(^{4,33}\)

The expression for $(A_2)_{LS}$ involves a double summation over components, and need not be elaborated here (however, see the example on association, section 4), except to note that for a polydisperse solute, $(A_2)_{LS}$ is not equal to the corresponding value $(A_2)_1$ obtained by osmotic pressure.\(^{4}\) Further, it may be noted that for polymer chains, for monodisperse solute, $A_2$ may be expressed in the form of Equation (57) (Yamakawa, p. 289; Yamakawa,\(^{20}\) p. 134),\(^{4,10,31}\)

$$A_2 = (A_2)_{ROD} F\left(\frac{L}{\theta, z}\right)$$

(57)

where $(A_2)_{ROD} = (\pi N_A L^2/4 M^2) d_{\text{thermo}}$ is the second virial coefficient for a rod-like chain with thermodynamic diameter $d_{\text{thermo}} = (3d_{\text{thermo}}/16\theta ) (3L/\pi \theta )^{1/2}$

is a thermodynamic interaction parameter, and $F(L/\theta, z)$ is a function that depends on chain conformation, with $F(L/\theta, 0) = F(0, z) = 1$. For uncharged solute, $d_{\text{thermo}}$ is zero at the Flory $\theta$ temperature, and increases to about twice the geometric diameter $d_{geo}$, for uncharged solute in so-called good solvents. In good solvents, $A_2M/[n] \approx 1$ for linear flexible chains, with $[n]$ the intrinsic viscosity.\(^{51}\) By comparison, for particles interacting through a hard-core potential, (Yamakawa,\(^{20}\) p. 181), Equation (58) applies

$$A_2 = \frac{4N_A V_{\text{particle}}}{M^2}$$

(58)

where $V_{\text{particle}}$ is the particle volume and $f$ is a parameter that depends on the particle shape, e.g. $f = 1$ for a sphere, and $f = L/4d_{geo}$ for a rod of diameter $d_{geo} \ll L$; $A_2M/[n] \approx 16/5$ for spheres. The behavior with charged solutes or particles is discussed in section 4.

Similar relations obtain for optically anisotropic polymers, but the coefficients are generally smaller, reflecting the origin of the scattering from fluctuations in the orientation of the scattering elements. Thus, for rod-like chains, (Yamakawa,\(^{20}\) p. 227)\(^{4,10,112}\) (Equations 59 and 60)

$$\Gamma_{V,c}(c) = [2(A_2)_{LS}M_{LS} + \cdots] + \left(4\beta^2 \frac{\Gamma_{V,c}(c)}{5}\right)$$

(59)

$$\Gamma_{V,c}(c) = \frac{(A_2)_{LS}M_{LS}}{4} + \cdots$$

(60)

or an eight-fold smaller leading term for depolarized scattering than obtains with polarized scattering.

The possible dependence of $P_{\infty}(\theta, c)$ and $H_{\infty}(\theta, c)$ on $c$ may complicate the extrapolation of data to infinite dilution, or the interpretation of data at a single concentration. For example, the initial tangent, given by Equations (61) and (62)

$$\frac{\partial [Kc/R_{\infty}(\theta, c)]}{\partial q^2} = M_{LS}^{-1/2} \left\{ \frac{\partial P_{\infty}(\theta, c)}{\partial q^2} \right\}$$

(61)
may depend on $c$ (the potential dependence of $P_{iso}(\theta, c)$ on $c$ is subsumed in the function $W_{iso}(\theta, c)$ in the second form); $\Gamma_{iso}$ may be expressed as a virial expansion in dilute solutions. For the range of $(R^2_c)_{LS}q^2$ normally accessible with polymer chains, plots of $KMc/\Gamma_{iso}(\theta, c)$ versus $q^2$ are usually observed to be essentially parallel for dilute solutions over a range of $c$, suggesting that $\partial W_{iso}(\theta, c)/\partial q^2$ is small—exceptions may occur for chains with very large $M$, and the corresponding larger range of $(R^2_c)_{LS}q^2$. Note that with the expression for $H_{iso}(\theta, c)$ for spheres given below, plots of $KMc/\Gamma_{iso}(\theta, c)$ versus $q^2$ would not be expected to be parallel, unlike the experience with flexible chain polymers. For convenience, the ratio of the initial tangent for small $\theta$ to the intercept $Kc/\Gamma_{iso}(0, c)$ at concentration $c$ is denoted $b(c)^2 = [c/R_{iso}(0, c)]^{-1}d[c/\Gamma_{iso}(\theta, c)]/dq^2$, so that, Equation (63)

$$b(c)^2 = \frac{(1/3)(R^2_c)_{LS} + c\Gamma_{iso}(c)\partial W_{iso}(\theta, c)/\partial q^2}{1 + c\Gamma_{iso}(c)}$$

Consequently, even if $\partial W_{iso}(\theta, c)/\partial q^2$ tends to zero (leading to parallel plots of $KMc/\Gamma_{iso}(\theta, c)$ versus $q^2$ over a range of $c$), $b(c)^2$ will not equal $(R^2_c)_{LS}$ unless $c\Gamma_{iso}(c) \approx 2(A_2)_{LS}M_{LS}c \approx 0$, as at very high dilution, or for a dilute solution with $(A_2)_{LS} = 0$.

For $\theta > 0$, the function $H_{iso}(\theta, c)$ may introduce an additional dependence on $\theta$, and for polymer chains, $P_{iso}(\theta, c)$ may vary with $c$, reflecting principally changes in the mean-square radius of gyration with $c$.\(^{(3, 3)}\) The behavior for spherical particles interacting through a hard-core potential provides an example of this behavior. In that case, (Guinier and Fournet,\(^{(14)}\) p. 48),\(^{(4)}\) Equation (64) holds

$$H_{iso}(\theta, c) = \frac{[P_{iso}(\theta', c)]^{1/2}}{P_{iso}(\theta, c)}$$

where $\sin(\theta'/2) = 2\sin(\theta/2)$, and $P_{iso}(\theta, c) = P_{iso}(\theta, 0)$ for this model. Consequently, $P_{iso}(\theta, c)H(\theta, c) = [P_{iso}(\theta', 0)]^{1/2}$, and $R_{iso}(\theta, c)/KMc \approx P_{iso}(\theta, 0)$ for large $(R^2_c)_{LS}q^2$ as expected.

For flexible chain polymers, the mean-square radius of gyration $(R^2_c)_{c}$ at concentration $c$ tends to its value $\bar{a}L/3$ obtaining under Flory $\theta$ conditions with increasing $c$, even in good solvents for which $(R^2_c)_{c}$ exceeds this value at infinite dilution.\(^{(3, 3)}\) A first approximation to $P_{iso}(\theta, c)$ and $H_{iso}(\theta, c)$ for flexible chain polymers in this situation is to use the relation for $P_{iso}(\theta, c)$ for a random-flight chain with the observed $(R^2_c)_{c}$ at concentration $c$ (as opposed to the value at infinite dilution), along with the above approximation for $H_{iso}(\theta, c)$\(^{(4, 113, 114)}\) Although this provides a qualitatively useful approximation, it may not be quantitatively correct, and should not be relied on if accuracy is critical; in one alternative, the Flory–Krigbaum pair potential (Flory,\(^{(29)}\) p. 519) has been used to estimate $H_{iso}(\theta, c)$.\(^{(115)}\) The effects of electrostatic interactions among charged spheres are discussed in section 4.

### 3 EXPERIMENTAL METHODS

#### 3.1 Instrumentation

Discussion of the instrumentation, alignment and calibration methods, and methods of treating data may be found in a number of places\(^{(1, 10, 18, 116, 117)}\) (see also Chu,\(^{(7)}\) p. 155) and only a brief account will be given here. Light scattering photometers with a variety of designs and special purposes are commercially available. These comprise several components, including:

1. the incident light source and its associated optics;
2. the light scattering cell;
3. the detector and its associated optics;
4. the electronic components associated with the detector.

In addition, the experiment could require specialized apparatus in special cases, e.g., filters to remove (most of) any fluorescence emission, means of controlling the temperature, etc.

Several factors are necessary in converting the response $G(\theta)$ from the detector to useful parameters in the analysis of static light scattering, including:\(^{(11, 117, 10, 18, 116, 118)}\)

1. the dependence of the scattering volume on angle and solvent;
2. the effects of attenuation of the incident or scattered rays;
3. the polarization state of the incident and scattered rays;
4. the relation of the detected signal to the Rayleigh ratio.

Most light scattering photometers make use of laser light sources, ranging from a few milliwatts to a hundred milliwatts or so in output power. Usually this is a plane-polarized state with the electric vector in the direction vertical to the scattering plane (the plane containing the incident and scattered rays), see below. The plane of polarization may then be rotated by rotation of a half-wave plate placed in the incident beam, providing a convenient tool for optical alignment. The detector optics are designed to control the angular acceptance.
of the scattered light and the horizontal and vertical dimensions of the scattering volume; the depth of the scattering volume is controlled by the width of the incident beam. One of a few optical designs is usually employed in the detector optics, and one of two general arrangements to make use of these relations may be found in practice: (i) the use of a single detector mounted on a goniometer for use over a range of scattering angles, and (ii) the use of a separate detector for each angle. The angular resolution and scattering volume must be known at each scattering volume to permit assessment of the Rayleigh ratio. In some designs this is facilitated by ensuring that the scattering volume has a vertical dimension smaller than that of the incident beam, but other procedures may be adopted. It is usually advisable to place a band-pass filter with a high transmission for the scattered light before the detector to minimize the effects of any fluorescence from the sample or stray light from sources other than the incident beam. Similarly, a band-reject filter may be used to assess the presence of fluorescence. It is also advisable to place a polarizing filter of some kind before the detector, and it is essential to do this if the anisotropic scattering is to be studied. Unfortunately, not all commercially available instruments provide the option of placing filters in the scattered beam.

Specialized instruments for examining the scattering profile in the Fraunhofer diffraction limit (very small scattering angles) have been constructed and are commercially available, e.g. see Weiner and Plantz for a discussion of some of these. The instruments differ principally in the manner of data collection: measurement of the intensity at an angle \( \theta \) (within a small span \( \delta \theta \)), or collection over an appreciable angular range \( \Delta \theta = \theta_{\text{max}} - \theta_{\text{min}} \), over a range of values for \( \theta_{\text{max}} \), see section 4 for further discussion. In some cases, these small angle measurements are augmented by scattering measurements at a larger angle (or angles), sometimes using light from a laser with excitation at more than one wavelength to provide scattering over a range of \( q \).

### 3.2 Methods

The optical clarification of the scattering sample is of paramount importance in obtaining reliable results in light scattering. The clarification should remove extraneous motes or "dust", undissolved polymer, gas bubbles, and any other scattering source not intrinsic to the sample of interest. At the same time, the clarification process should not cause unwanted removal of a portion of the sample. Often, in the final stages of clarification, the number of extraneous motes is very small, giving the appearance of a few widely separated bright spots in the sample when the scattering is viewed at a small scattering angle. In some instruments the scattering volume is made small in a strategy to reduce the number of extraneous particles in the scattering volume to zero or one for the most part, owing to the wide separation of any remaining extraneous motes. Since the scattering will then normally be rather different for these two states, it is possible to discriminate against the scattering from the extraneous matter. A similar strategy is sometimes employed in computer-aided data acquisition, by collecting data over a time interval that is long in comparison with the timescale for normal intensity fluctuations, but shorter than the timescale for fluctuations due to diffusion of the extraneous matter. The stronger than normal scattered intensity due to the motes may then be discriminated against in the data collection.

In some cases, the experimental data encompass a limited range of angles (e.g. two or three), leading to the use of "dissymmetry methods" to analyze scattering data in the RGD regime, following a procedure introduced early in the use of light scattering to characterize solute dimensions. Often, one of the scattering angles is taken to be 90°. The dissymmetry \( Z(\theta_1, \theta_2) = G(\theta_1)/G(\theta_2) \) and scattering volume \( V(\theta) \) for \( \theta_1 < \theta_2 \), may be used to estimate \( (R_G^2)_{\text{LS}}/\lambda^2 \) (with \( \lambda = \lambda_0/n_{\text{medium}} \)) provided a model is available, including the effects of molecular-weight heterogeneity. The dissymmetry method may not be applied beyond the RGD regime, because then \( Z(\theta_1, \theta_2) \) is not generally a single-valued function of \( (R_G^2)_{\text{LS}}/\lambda^2 \). The use of supplementary angles \( \theta_2 = \pi - \theta_1 \) will usually make the scattering volumes equal at the two scattering angles, simplifying the analysis. Note that in general, \([R_0\nu(\theta_1, c)/c]^0/[R_0\nu(\theta_2, c)/c]^0 \neq R_0\nu(\theta_1, c)/R_0\nu(\theta_2, c)\), requiring extrapolation to infinite dilution to determine \( Z(\theta_1, \theta_2) \). In the original dissymmetry method, \( \theta_1 \) and \( \theta_2 \) were equal to 45° and 135°, respectively, so that \( V(\theta_1) = V(\theta_2) \) in a convenient cell geometry (e.g. cylindrical), and \( Z(\theta_1, \theta_2) = G(\theta_1)/G(\theta_2) \) (see Kerker, p. 432). The value of \( (R_G^2)_{\text{LS}}/\lambda^2 \) may then be used to estimate for \( P_{\nu}(\theta_1, 0) \) for the assumed model with the correction needed to deduce \([R_0\nu(0, c)/c]^0 \) from \([R_0\nu(\theta_3, c)/c]^0 \) determined at some particular angle, e.g. \( \theta_3 = 90° \) in the original method. In some cases, only two scattering angles are used, one being fairly small, and the other being 90°, with due attention to the ratio \( V(\theta_2)/V(\theta_1) \). Tables to assist this treatment are available for a number of models, or the relations needed may be readily calculated as required using a desktop computer. The use of \( P_{\nu}(\theta, 0) \) for a linear chain to estimate \( (R_G^2)_{\text{LS}}/\lambda^2 \) by the dissymmetry ratio for a chain that is branched may introduce an error in the estimate for \((R_G^2)_{\text{LS}}/\lambda^2 \) if \((R_G^2)_{\text{LS}}/\lambda^2 \) exceeds about 1. For example, the deviations shown in Figure 5 would...
lead to increasingly serious overestimation of \( (R_G^2)_{LS} \) with increasing \( (R_G^2)_{LS} q^2 \). An example of this effect may be seen for \( Z(45, 135) \) versus \( (R_G^2)_{LS}/\lambda^2 \) for monodisperse linear chains and regular four-arm star branched molecules for the random-flight model. \(^{125}\)

Finally, other methods of data treatment may be found in the literature. Examples include Guinier plots of \( \ln(R_{Vv}(\theta, c))/Kc \) versus \( q^2 \), based on the approximation \( P_{Vv}(\theta, 0) = \exp(- (R_G^2)_{LS} q^2/3) \) (Guinier and Fournet,\(^{24}\) p. 21), Casassa plots of \( Kc/R_{Vv}(\theta, c) \) versus \( q \) for rod-like scatterers, based on Equations (42) and (43),\(^{18,56}\) Porod plots of \( q^2 R_{Vv}(\theta, c)/Kc \) versus \( q \), based on \( P_{Vv}(\theta, 0) \) for worm-like chains, see below (Yamakawa,\(^2\) p. 122),\(^{18,52,124}\) and plots of \( (Kc/R_{Vv}(\theta, c))^{1/2} \) versus \( q^2 \), introduced by the author.\(^{10}\) These are useful for analysis of data on dilute solutions under special circumstances. Thus, the Guinier plot was devised for use with the scattering from particles polydisperse in size and shape, for which a more detailed treatment was not feasible; as seen in Figure 3, the actual scattering behavior is usually not represented by the exponential function over a range of \( q \) (unless \( (R_G^2)_{LS} \) is very small); with the exponential function providing a useful approximation to larger \( R_G^2 \) for spheres than for the other examples in Figure 3. The Casassa plot is only useful for very long rod-like solutes for which the asymptotic behavior for large \( q \) may dominate the scattering for all accessible \( q \), in which case the tangent provides length per unit mass. Similarly, the Porod plot is designed to elucidate the behavior at large \( q \) and may, for example reveal the persistence length of a semiflexible (worm-like) chain if large enough \( q \) can be attained; the Porod plot is usually of most interest with the scattering from X-ray or neutron radiation owing to the need to reach large \( q \). The “square-root” plot is based on the observation that for a linear monodisperse random-flight linear chain model, for which \( R_G^2/M \) is independent of \( M \), Equation (65)

\[
P_{iso}(\theta, 0)^{-1/2} = 1 + \frac{R_G^2 q^2}{6} + \cdots \quad (65)
\]

facilitates evaluation of the initial tangent\(^{125}\) and hence \( R_G^2 \), because in this case the coefficient of \( q^4 \) tends to be smaller in this expansion than in the expansion for \( P_{iso}(\theta, 0) \). Clearly, the use of \( P_{Vv}(\theta, 0)^{-1/2} \) to facilitate data analysis should be applied only under appropriate conditions, e.g. it would be inappropriate for the polydisperse solute with a most-probable distribution of molecular weight, see below. Similarly, for monodisperse spheres, \( P_{iso}(\theta, 0) \) is closely approximated by \( \exp(- R_G^2 q^2/3) \) for \( R_G^2 q^2 < 2 \), with the deviations growing for larger \( R_G^2 q^2 \), see Figures 3 and 6; this fit is less satisfactory for spheres heterogeneous in size, as may be deduced from Figure 4.

4 EXAMPLES

4.1 Static Scattering and Size Separation Chromatography

The application of light scattering and differential refractometry in on-line analysis of the eluent in size exclusion chromatography (SEC) which separates the eluent by size provides a powerful tool for analysis and characterization and has found wide application, e.g. see Lloyd et al.\(^{126}\) and Barth and Flippen\(^{127}\). Examples include SEC and flow field-flow chromatography (FFF). Since the solute concentration is usually very low in the eluent, it is normally assumed that \( c f_{Vv}(c) \approx 0 \) for all elution volumes, or a correction is made based on an estimate for \( A_2 M_c \). With optically isotropic homopolymers, the response \( h_c \) of the differential refractometer at elution volume \( V_e \) permits evaluation of the weight fraction \( w_e = h_c/ h_c \) for each \( V_e \) (excepting possible end-group effects low \( M \)). Then, the static (excess) scattering data \( [R_{Vv}(\theta, c)]_e \) at each elution volume may be used to compute the molecular weight as \( M_e \approx [R_{Vv}(\theta, c)]_e/Kc w_c [P_{Vv}(\theta, c)]_e \), given the concentration \( c \propto h_e \) and \( \partial n/\partial c \). The factor \( [P_{Vv}(\theta, c)]_e \) may be evaluated using either an experimental estimate for \( [P_{Vv}(\theta, c)]_e \) from on-line measurements of \( [R_{Vv}(\theta, c)]_e \) as a function of \( \theta \), or as [\( [P_{Vv}(\theta, c)]_e \approx 1 \) if \( \theta \) is small enough. In addition, on-line measurements over a range of scattering angles allow determination of \( (R_G^2)_e \) as a function of \( V_e \). In some instruments, \( [R_{Vv}(\theta, c)]_e \) is measured only at a single angle, e.g. 90°, with the resulting need to estimate \( [P_{Vv}(\theta, c)]_e \) at that angle being a possible source of inaccuracy. In other instruments, it is possible to measure the scattering at two or three angles, permitting the use of dissymmetry methods to estimate \( [P_{Vv}(\theta, c)]_e \) based on an assumed functional form, see for example the discussion of dissymmetry methods above. Comparison of \( M_e \approx w_e M_c \) calculated from the data on the eluent with \( M_e \) determined directly on the unfractonated polymer provides a self-consistency check.

An example of the use of multangle light scattering with SEC to study the dimensions of poly(di-n-hexylsilane), (PDHS), and poly(phenyl-n-hexylsilane), (PPHS), is given in Figure 7 (from Berry and Cotts\(^{11}\) and Cotts\(^{126}\)). Figure 7(a) gives \( M_e \) and \( (R_G^2)_e \), resulting from analysis of the multiangle scattering data, and Figure 7(b) gives the response from the differential refractive index detector, normalized to give the same peak response. As expected from the mechanism of SEC, the values of \( (R_G^2)_e \) are the same at a given elution volume for the two polymers, but the values of \( M_e \) differ. If the elution volume increments are small enough, then \( (R_G^2)_e/M_e \) is expected to approximate the value for a monodisperse chain. Analysis of these data permitted assessment of the difference in \( R_G^2/M \) for these polymers, revealing the substantially
larger persistence length for PPHS, owing to the effects of the phenyl substituent.

Another example is provided by the analysis and characterization of branched macromolecules. Certain polymerizations are expected to produce a randomly branched chain structure, in which the number of branch nodes and their placements are randomly distributed among the chains in the ensemble (Flory, p. 347). In such a case, it is not possible to achieve a simultaneous separation by the number \( m \) of branch nodes and overall molecular weight \( M \), as each molecule in the ensemble is distinct in this respect. One could conceive of a separation by either \( p \) or \( M \), with each separated component then narrow in one feature and polydisperse in the other. Analysis by SEC of such a polymer suggests that although the polymer at each elution volume \( V_e \) is polydisperse in both \( p \) and \( M \), the distribution in \( M \) is much narrower than that in \( p \). Consequently, on-line determination of \( M_w \) and \( (R_G^2)_{LS} \) of the eluent for heterodisperse linear (●) and branched polymers (○) resulting from analysis of the multiangle scattering data, with the dashed line and solid curves giving power law and polynomial extrapolations, as discussed in the text. The ratio \([R_G^2]_{LS}/[R_G^2]_{LIN}\) from the data in part (a), using the powerlaw (○) and polynomial (●) extrapolations to estimate \([R_G^2]_{LIN}\). (Adapted from figures in Jackson et al.)

In this approximation, theoretical expressions\(^{(130)}\) for \( g \) for a polymer monodisperse in \( M \), with a random distribution in \( p \), would be used to estimate \( p \); the formula, involving summations, is readily calculated with a desktop computer. An example of data of this type is given in Figure 8 for samples of linear and branched PMMAs.\(^{(131)}\) According to the preceding, these data may be used to estimate \( g_e \) and hence the branching frequency, as a function of molecular weight, provided a reliable estimate for \([R_G^2]_{LIN}\) is available. As demonstrated in Figure 8, the latter may not be readily available at the higher molecular weights encountered with branched chains. For the data in Figure 8, the dependence of \([R_G^2]_{LIN}/M_w\) on \( M_w \) is stronger than anticipated for the larger \( V_e \), chain.
perhaps reflecting the effects of increased molecular weight dispersity with increasing \( V_e \) with the column set utilized. Two extrapolations have been presented and used to estimate \( g_e \), with the true value likely to be somewhere between these estimates.

The size distributions in vesicle preparations similar to those described in the next section have been examined using FFFC.\(^{132}\) Although a procedure involving simultaneous determination of the scattering and the concentration of the eluent could have been followed, only an (excess) instrument response \( G(\theta, c) \) proportional to \( R_{\text{GG}}(\theta, c) \) was determined as a function of elution volume. Owing to the low concentrations used, such that \( 2A_2MC \ll 1 \), it was assumed that \( c\Gamma(c) \approx 0 \) in calculations of the number fraction distribution \( n_\mu \). Then, since \( [R_{\text{GG}}(\theta, c)]_\mu = KM_\mu^2 P_\mu(\theta, 0) \mu N_A \) for each fraction in this approximation, with \( n_\mu \) the number concentration, the number fraction was computed from Equation (66):

\[
n_\mu = \frac{G_\mu(\theta, c)/M_\mu^2 P_\mu(\theta, 0)}{\sum G_\mu(\theta, c)/M_\mu^2 P_\mu(\theta, 0)} \tag{66}
\]

In the analysis, \( P_\mu(\theta, 0) \) was fitted to the expression for a hollow shell (the RGD approximation being adequate), to give the outer radius \( R_\mu \) for each eluent fraction, on the assumption that the shell thickness \( \Delta_{sh} \) was invariant with \( R_\mu \), and could be evaluated for the unfractionated polymer, as described in the next section. The expression given above was then used to compute \( M_\mu \), using \( R_\mu \), \( \Delta_{sh} \), and the solute specific volume \( v_2 \), to permit evaluation of \( n_\mu \) for each \( R_\mu \). As anticipated from the mechanism for FFFC, \( R_\mu \) increased linearly with elution volume, except for early elution times, for which the weak scattering may have introduced error in the evaluation of \( R_\mu \).

### 4.2 Light Scattering from Vesicles and Stratified Spheres

Many unilamellar vesicles comprise a single closed shell bilayer.\(^{133}\) They may be prepared with a spherical shape, and that shape may be further stabilized by a slight imbalance in the compositions of the vesicle interior and exterior, to create a (small) positive osmotic pressure on the interior. Such vesicles provide an example of a shell-like structure, with a shell thickness \( \Delta_{sh} \) generally much smaller than the outer radius \( R \) of the vesicle. The thickness \( \Delta_{\text{planar}} \) of an analogous planar bilayer may be computed as \( \Delta_{\text{planar}} = 2V_{\text{lipid}}/A_{\text{lipid}} \), where \( V_{\text{lipid}} \) and \( A_{\text{lipid}} \) are the volume and cross-sectional area of the molecules in the bilayer, respectively. It is expected that \( \Delta_{sh} \approx \Delta_{\text{planar}} \) with increasing \( R \). For a shell, \( \Delta_{sh} \) may be calculated from the ratio of its volume \( v_2 M/N_A \) to its surface area \( 4\pi R^2 \), where \( v_2 \) is the specific volume of the shell, Equation (67):  

\[
n_{sh} = \frac{v_2 M}{N_A} 4\pi R^2 \Delta_{sh} \left\{ 1 - \left( \frac{\Delta_{sh}}{R} \right)^3 + \frac{(\Delta_{sh}/R)^2}{3} \right\} \tag{67}
\]

Consequently, the ratio of \( v_2 M \) to \( R_G^2 \) may be used to approximate \( \Delta_{sh} \) for spherical, monodisperse vesicles. The relation \( P_{\Gamma}(\theta, 0) \) given above for a shell may be used to compute \( R_G^2 \) from Equations (68) and (69):

\[
R_G^2 = R^2 \left( \frac{3}{5} \frac{1}{1 - (\Delta_{sh}/R)^3} \right) \tag{68}
\]

\[
R = \frac{(R_G^2)^{1/2}}{[1 + (1/2)\beta + (1/20)\beta^2 + \cdots]} \tag{69}
\]

where \( \beta = v_2 M/4\pi N_A R_G^2 \). Equation (70) follows:

\[
\Delta_{sh} = \frac{v_2 M}{4\pi N_A R_G^2} \left( 1 + \left( \frac{1}{3} \beta^2 + 0.06\beta^3 + \cdots \right) \right)^{-1} \tag{70}
\]

and inspection shows that \( \Delta_{sh} \approx v_2 M/4\pi N_A R_G^2 \) and \( R \approx (R_G^2)^{1/2} \) to a good approximation for \( \beta \approx 1 \), with correction factors readily calculated using experimental data for \( \beta \). Light scattering data on unilamellar vesicles of phosphatidylcholine prepared over a range of size were analyzed to obtain \( R \) and \( \Delta_{sh} \), after extrapolation to infinite dilution, with results which gave \( \Delta_{sh} \), a weakly decreasing function of increasing \( R \), tending to \( \Delta_{\text{planar}} \) (\( \Delta_{sh} \approx 3.5 \) nm and \( R \approx 34-40 \) nm for the several samples examined).\(^{134,135}\)

Size distributions for vesicles with characteristics similar to those discussed above have been reported from inversion of \( P_{\Gamma}(\theta, c) \), using a nonnegative least squares fit over a predetermined selection of radii, using \( \Gamma_{\text{GG}}(\theta, c) \) for a vesicle, and the assumption that \( c\Gamma(c) \approx 0 \) in the analysis.\(^{136}\) The authors report no significant difference between the use of the RGD approximation and the Mie theory for hollow vesicles, owing to the small radius (\( \approx 50 \) nm), and although the distribution functions obtained were reproducible, they did differ significantly from those obtained by inversion of dynamic light scattering data. The latter gave a broader distribution, especially for larger particle radii. Among possible reasons cited for this discrepancy, it was noted that the experimental time required for dynamic data acquisition was much longer than that for static data (hours compared with minutes), and that interparticle aggregation may have intervened during that longer time to introduce errors in the dynamic data. Another example of an analysis on hollow polystyrene spheres dispersed in water\(^{107}\) produced the results shown in Figure 9, again under the assumption that \( c\Gamma_{\text{GG}}(c) \approx 0 \). The spheres had a radius of about 0.23 \( \mu \)m, large enough to require the use of Mie theory in the analysis of the data at the larger \( q \); the difference between the use of Mie theory and the RGD
approximation is shown in Figure 9. The size distribution obtained from dynamic light scattering was shifted to smaller sizes, see Figure 9(b), for reasons not definitively understood.

Block copolymers may form a core-shell micelle in solution, with a resemblance to a vesicle or hollow shell, but with scattering from the core as well as the shell.\(^{137}\) In these cases, for a system with micelles nearly monodisperse in size and structure, \(P_{Vv}(\theta, c)\) would be given by Equation (48) for a shell in the RGD regime or an appropriate relation for the Mie regime (Kerker,\(^{21}\) p. 189), with scattering similar to that for a vesicle, but with a core with a refractive index different from that of the solvent. For example, in this case, since \(\Delta^2_{AB} = 0\), for the centrosymmetric micelle (Equation 71)

\[
(R^2_G)_{LS} = \left[ \frac{3}{5} \left( \alpha R^2_A + (1 - \alpha) \frac{[R^2_B - R^2_A]}{[R^2_B - R^2_A]} \right) \right] (71)
\]

![Figure 9](image)

Figure 9 Example of the scattering from an aqueous dispersion of heterodisperse hollow polystyrene spheres. (a) Scattering function and fits thereto using the RGD approximation and the Mie theory. (b) Number fraction distribution of particles with a given size deduced from the inversion of the scattering function using the RGD approximation and the Mie theory; an estimate determined from analysis of the dynamic light scattering is included for comparison. (From figures in Strawbridge and Hallett.\(^{107}\))

with the relation discussed above for a sphere of radius \(R_A\) coated by a shell of (outer) radius \(R_B\) and thickness \(\Delta = R_B - R_A\), and \(x = w_A\psi_A / [w_A\psi_A + (1 - w_A)\psi_B]\). Since the refractive increments \(\psi_A\) and \(\psi_B\) may be either negative, positive or zero, as may \((R^2_G)_{LS}\), which consequently does not bear any simple geometric significance. Owing to symmetry, \((R^2_G)_{LS}\) for a sphere with more complex but spherically symmetric distribution \(\psi(r)\) of refractive index increment and density \(\rho(r)\) about the center of mass may be expressed by converting the summations used above in the RGD approximation to integrals, Equation (72):\(^{21}\)

\[
(R^2_G)_{LS} = \int_0^\infty \frac{r^4\psi(r)\rho(r)dr}{r^2\psi(r)\rho(r)dr} \quad (72)
\]

For example, the preceding expression results from separating the integrals into two parts, from 0 to \(R_A\), and \(R_A\) to \(R_B\).

### 4.3 Scattering from Very Large Particles

As noted above, for very large spheres, with both \(\eta \gg 1\) and phase shift magnitude \(\alpha(n - 1) > 10\), \(P_{Vv}(\theta, c)\) reduces to the form for Fraunhofer diffraction from a circular aperture (or opaque disk), with the result that an exact integral expression may be written for the inversion of \(P_{Vv}(\theta, c)\) to obtain the size distribution in terms of the scattered intensities. Thus, in this treatment, use is sometimes made of the expression,\(^{119,132}\) Equation (73)

\[
L(x_1, x_2) = \frac{x_2}{x_1} s \frac{2J_1(s)}{s} ds = \int_0^\infty \left[ J_0^2(x_2) + J_1^2(x_2) - J_0^2(x_1) - J_1^2(x_1) \right] \quad (73)
\]

In this respect, an apparatus is used with a series of concentric-ring photodiodes, with each photodiode spanning successive angular increments. Thus, the forward scattering intensity is determined over a set of annular rings in this apparatus, rather than as a function of \(\theta\), with the function \(L(\theta_1, \theta_2)\) representing the fraction of the intensity incident on a particle scattered between angles \(\theta_1\) and \(\theta_2\). The function \(L(0, \theta)\) exhibits a series of plateaus for values of \(\theta\) for which \(J_1(\alpha\theta) / \alpha\theta = 0\), the first three of which are given by \(\alpha\theta\) equal to 3.83, 7.02 and 10.17, e.g. see Bohren and Huffman,\(^{133}\) p. 111; van de Hulst,\(^{22}\) p. 110; Weiner,\(^{119}\) Swithenbank et al.\(^{138}\) In practice, the available angular range is adjusted for the set of ring photodiodes with fixed geometry by using a series of lenses of differing focal length \(f\) to manipulate the angular range, with \(\theta \approx rf / r\), where \(r\) is the radial position of the light on the photodiode. The maximum angle used should be large enough to encompass essentially
all of the scattering, for example to avoid skewing the measurement to the larger components in a polydisperse mixture, a problem called vignetting in some of the specialized literature in this area;\(^{138}\) however, see below for an example of a related problem if the minimum angle is too large. Equation (74) applies to the analysis of a polydisperse sample (with \(\sin(\vartheta) \approx \vartheta\))\(^{119,138}\)

\[
L(\vartheta_1, \vartheta_2) \propto \sum_{\mu} n_{\mu} a_{\mu}^2 \left( J_0^2(\alpha_{\mu} \vartheta_1) + J_1^2(\alpha_{\mu} \vartheta_2) \right) - \left( J_0^2(\alpha_{\mu} \vartheta_1) + J_1^2(\alpha_{\mu} \vartheta_1) \right) \tag{74}
\]

where \(n_{\mu}\) is the number fraction of spheres with radius \(R_{\mu}\). In practice, the sum over \(\mu\) is approximated by a small number of discrete “components”, each of these actually representing an average over components in a “size class” determined by the mean radius of the detector ring and the focal length of the lens in use.\(^{119}\)

As mentioned above, a systematic consistent discussion of measurements in the Fraunhofer diffraction regime may be found in Koo and Hirlemann\(^ {92}\) for the representative optics and inversion methods. Instruments collecting the scattered light over a small angular increment at a given \(\vartheta\) are considered, along with instruments collecting light from some small angle \(\vartheta_{\text{min}}\) through angles up to \(\vartheta\); both types are used in practice. The forms of the integral expressions used in the inversion depend not only on the optical arrangement, but also on the number of times an integration by parts is used to develop the integral equation, with consequent change in the way data are processed in the inversion. In the ideal case, the accuracy of the inversion would not depend on these factors, but with real data, containing noise, and limited to a range of \(\vartheta\) by instrument design, these factors usually will affect the outcome. In addition, the method used to present the scattering medium (either as a dispersion in a fluid, or an aerosol) may affect the results. In this analysis, the expression for \(R_{\vartheta\varphi}(\vartheta, c)\) in the Fraunhofer limit is recast as an integral, Equation (75)\(^ {92}\)

\[
\vartheta^2 R_{\vartheta\varphi}(\vartheta, c) \propto \int_0^\infty k_{ab}(\alpha, \vartheta) \alpha^b n(\alpha) \, d\alpha \tag{75}
\]

where \(\alpha = 2\pi R/\lambda\), \(n(\alpha)\) is the (number) fraction of spheres with radius between \(R\) and \(R + dR\) (for fixed \(\lambda\)), the factors \(\vartheta^a\) and \(\alpha^b\) account for possible variation of the aperture over which the scattering is collected and the conversion to distributions in terms of particle volume \((b = 2)\) or area \((b = 1)\), respectively, and \(k_{ab}(\alpha, \vartheta)\) is the appropriate scattering function for the particle. For spheres, (with \(\sin(\vartheta) \approx \vartheta\)), Equation (76) applies

\[
k_{ab}(\alpha, \vartheta) = \frac{J_2^2(\alpha \vartheta)}{\vartheta^2 - a \alpha^2 b^2} \tag{76}
\]

This expression may then be inverted to obtain \(\alpha^b n(\alpha)\) for each \(\alpha\) as an integral over \(\vartheta\) (from 0 to \(\infty\)) of a kernel comprising functions of \(\alpha \vartheta\) and derivatives of \(\vartheta^2 R_{\vartheta\varphi}(\vartheta, c)\). The result may be cast in several forms, depending on \(a, b, c\), and whether use is made of integration by parts in obtaining the relation used in the inversion. The required range of \(\vartheta\) is, of course, nonphysical, but as the kernel involved reduces to essentially zero with increasing \(\vartheta\), the effect of the nonphysical upper limit on \(\vartheta\) is usually nil. The inversion of noise-free scattering data over a span in \(\vartheta\) typical of commercially available photometers is considered by Koo and Hirlemann\(^ {92}\) for five different arrangements and a range of particle sizes (mean diameters of 7–506\(\mu\)m) over a certain distribution of sizes given by a log-normal function in the particle area. Several statistical measures of the fit of the inversion to the starting size distribution were evaluated in order to arrive at the following principal conclusions in this idealized comparison: (i) the various methods are essentially equivalent over a relatively narrow range of particle size, but differ markedly for either small or large particles, (ii) none of the methods provide a satisfactory representation of the distribution of the smaller particles, and (iii) the methods vary considerably in their performance for distribution of larger particles. These results suggest that whereas the response may be reproducible, and therefore of use as a quality control protocol, the absolute distribution should be accepted with caution.

An example of the comparison of the size distribution deduced for some aerosols using an apparatus of the type described above with \(L(\vartheta_1, \vartheta_2)\) determined over a set of angles is shown in Figure 10, including results obtained by inversion of \(R_{\vartheta\varphi}(\vartheta, c)\), and by fitting \(R_{\vartheta\varphi}(\vartheta, c)\) with an assumed size distribution.\(^ {139}\) An example of the effect of the choice of the focal length \(f\) of the lens used on the analysis is illustrated in Figure 11 for the scattering from polydisperse glass beads with a size distribution (20–170\(\mu\)m) calibrated by microscopic measurements on a large sample of the beads (National Institute of Standards and Technology (NIST) Standard Reference Material 1004).\(^ {138,140}\) Data were taken in the Fraunhofer regime (\(\bar{\eta} \approx 1.146\) and phase shift magnitude \(a[\bar{n} - 1] \approx 40\)) with both 100 and 300-mm focal length lenses. Whereas the latter fitted the reported size distribution well, except for the largest size, the data with the smaller focal length lens did not afford a measurement at small enough \(\vartheta\) to permit a satisfactory assessment of the population of the larger beads.

As mentioned above, the scattering from large particles immersed in a solvent such that \(\bar{\eta} \approx 1\) may not be in the Fraunhofer regime, but rather may exhibit anomalous diffraction. The assumption that Fraunhofer diffraction
applies may lead to serious error in the size distribution determined from the angular profile of the scattered light. An example of this is given in Figure 11, showing data obtained with the 100-mm focal length lens and dispersions in different liquids to provide two values of $n$ close to unity ($n \approx 1.02$ and 1.08).\textsuperscript{138,140} The data on $L(\theta_1, \theta_2)$ show the profound effect of $n$. The expressions for the anomalous scattering regime were used to compute $L(\theta_1, \theta_2)$ using the size distribution, with the results being a reasonable fit to the data for both values of $n$. Further, the data for $n \approx 1.02$ were inverted under two assumptions: the use of the relations for the Fraunhofer and anomalous scattering regimes. Whereas the latter was in reasonable agreement with the result obtained with data in the Fraunhofer regime ($n \approx 1.146$), the use of the expressions for the Fraunhofer regime gave erroneous results, as expected.

4.4 Intermolecular Association

Intermolecular association is not uncommon in macro-molecular solutions or dispersions of particles, especially in aqueous solvent. In general, two forms may be encountered in the extreme: association involving two or more components at equilibrium at any given concentration; and metastable association, in which the components present depend on processing history, but do not change sensibly with concentration in the range of interest for light scattering. Of course, intermediate situations may also occur.

Aside from any criterion imposed by the anticipated nature of the solute, the experimenter may have little reason to suspect association from the dependence of the scattering on concentration in the case of a metastable association. In some cases of metastable association, the molecular weight deduced from extrapolation of $Kc/R_{Vv} (\theta, c)$ to zero $q$ and infinite dilution will depend on temperature or solvent, revealing the association. An example of this sort in which the nature of intermolecular association of a solute with a helical conformation was elucidated by the use of static and dynamic light scattering as a function of temperature is given by Yue et al.\textsuperscript{141} In the cited case, the scattering at any given temperature exhibited "normal" behavior and could not have been analyzed to reveal association if taken alone. In a different and somewhat unusual, but not unique, example, it has been reported that $Kc/R_{Vv} (\theta, c)$ is linear in $q^2$, albeit giving a molecular weight that is much larger than the true value of $M_w$ for the solute.\textsuperscript{142} This was observed with a system that formed a gel at a higher solute concentration, suggesting that the observed scattering behavior reflects the anticipated $P_{Vv} (\theta, c)$ for a randomly branched polymer.\textsuperscript{6} More frequently, with intermolecular association involving flexible chain polymers, $Kc/R_{Vv} (\theta, c)$ exhibits enhanced scattering at small $q$. This is often taken as evidence for the presence of an aggregated species mixed with solute that is either fully dissociated, or much less aggregated. Although reasonable, it should be realized that such an interpretation is not unique.

A well-defined analysis is possible, at least in principle, for a case with equilibria among otherwise monodisperse monomers, dimers, etc. e.g. the equilibria obtaining among monomers, dimers, and tetramers for hemoglobin in solution.\textsuperscript{143,144} Equilibrium association can lead to nonparallel plots of $Kc/R_{Vv} (\theta, c)$ versus $q^2$ if the species are large enough. In the ideal situation, the ratio of $R_q^2$ for the aggregates to the unimer would be precisely known, as would be the effect of association on $A_2$, permitting an assessment of the equilibrium constant for the association for a given model.\textsuperscript{144} An illustrative example of the
Figure 11  Example of the scattering from heterodisperse glass particles dispersed in different solvents to span a range of $\bar{n}$. (a) Scattering function (points and solid curve) obtained using a lens with a 100-mm focal length and solvents to give the indicated $jQn/NUL_1$, and fits thereto using the Mie theory and the known size distribution function (dashed curves). (b) Cumulative weight distribution of particles with a given size deduced by several methods: solid squares, from microscopic measurements (the “known” distribution function), as reported by NIST (see text), open squares and open diamonds, from inversion of the scattering function using the Mie theory for $jQn/NUL_1$, and two lenses, with focal lengths 300 mm (squares) and 100 mm (diamonds), and circles, for solvents to give $|\bar{n} - 1| \approx 0.02$ calculated with the assumption of Fraunhofer diffraction (solid circles and dashed line) or anomalous diffraction (open circles and solid line). (Adapted from figures in Brown et al.\textsuperscript{140})

effects of association is given in Figure 12. The example was calculated on the assumption that a monodisperse linear flexible coil chain of molecular weight $M$ may undergo end-to-end dimerization to create a linear chain of molecular weight $2M$, with equilibrium constant $K_{eq}$. Further, it was assumed that $\partial \ln R_G^2 = \partial \ln M = \epsilon$, and $\partial \ln A_2 = \partial \ln M = \gamma$, with $\epsilon = 2(2 - \gamma)/3$, following the usual approximation for flexible chain polymers (see Yamakawa,\textsuperscript{20} p. 146; Flory,\textsuperscript{29}, p. 536).\textsuperscript{31} Finally, in addition to the expressions for $M_{LS} = M_w$, $(R_G^2)_{LS} = (R_G^2)_2$, and $P_{\nu\nu}(\theta, c)$ given above, $(A_2)_{LS}$ was calculated as,\textsuperscript{10,18} (Equation 77)

$$\frac{\sum \sum w_\mu M_\mu w_\nu M_\nu (A_2)_{\mu\nu}}{M_w} (A_2)_{LS} =$$

where $(A_2)_{\mu\nu}$ is $A_2$ for monodisperse component $\mu$, and $(A_2)_{\mu\nu}$ is approximated by $[(A_2)_{\mu\nu}(A_2)_{\nu\nu}]^{1/2}$.\textsuperscript{10,18} With the use of these relations, Equation (78–82)

$$M_w = M(2 - \zeta)$$  \hspace{0.5cm} (78)

$$R_G^2 \equiv R_G^2 = \frac{[\zeta + 2 + (1 - \zeta)]}{(2 - \zeta)}$$  \hspace{0.5cm} (79)
Figure 12 Scattering functions for an illustrative example of a flexible chain polymer undergoing end-to-end dimerization. (a) Dependence on angle, calculated as discussed in the text for a reduced equilibrium constant $K_{eq} = 0.1$ and the indicated values of $(A_2)_0 M c$, with the constant equal to zero or 0.2 for the solid and dashed curves, respectively. (b) Scattering extrapolated to zero angle as a function of $(A_2)_0 M c$ for the indicated values of $K_{eq}$.

$P_{Vv} (\theta, c) = \left\{ \frac{a[P_{Vv} (\theta, c)]_M + 2(1 - \zeta)[P_{Vv} (\theta, c)]_M}{2 - \zeta} \right\}$

(80)

$(A_2)_{LS} M_w = \frac{(A_2)_0 M c [\zeta + 2^{1 + \gamma/2}(1 - \zeta)]^2}{2 - \zeta}$

(81)

$\zeta = \left\{ \frac{K_{eq}}{2(A_2)_0 M c} \left( \frac{1 + 4(A_2)_0 M c}{K_{eq}} \right)^{1/2} \right\}$

(82)

where $\zeta$ is the degree of association, and $P_{Vv} (\theta, c)$ is given by the expression in Table 2, with $u$ replaced by $2u$ for $[P_{Vv} (\theta, c)]_M$. The calculations were completed for $\varepsilon = 7/6$ ($\gamma = 1/4$), over a range of $(A_2)_0 M c$ and $K_{eq} = (A_2)_0 M^2 K_{eq}$. It may be noted that for large $K_{eq}$, the extrapolation to obtain the true molecular weight $M$ at infinite dilution ($\zeta = 0$) may not be possible and the experimenter may erroneously assume that the molecular weight of the polymer at infinite dilution is $2M$. The effect of the association in producing nonparallel $Ke/R_{Vv} (\theta, c)$ versus $q^2$ for data at different concentration is illustrated in Figure 12.

The situation is usually more complex than the idealized equilibrium association, and analysis of such behavior is sometimes facilitated by an approximate representation with a few “pseudo” components (often two), each of which dominates the scattering over a limited range of $q$, with $M$, $A_2$, and $P_{Vv} (\theta, c)$ replaced by their light scattering averages for each pseudocomponent. That is (Equation 83),

$R_{Vv} (\theta, c) \approx \sum_{\mu} [R_{Vv} (\theta, c)]_\mu$

(83)

where the subscript “$c$” indicates that the parameters $M$ and $A_2$, and the character of the function $P_{Vv} (\theta, c)$ may all depend on $c$ through the dependence of the state of aggregation on $c$; note that this form does not properly account for the averaging among scattering elements, but it can provide a useful approximation if the components are few and widely separated in size. The analysis of the suspected association by this relation is similar to the determination of the size distribution discussed above in the absence of association, but is made more complex because it involves data over a range of $c$, with concentration-dependent parameters, and the function $P_{Vv} (\theta, c)$ may not be the same, or even known, for all of the aggregates present, and may depend on $c$. In some of the literature on small-angle X-ray scattering, it has been common to assume that $P_{Vv} (\theta, c) \approx \exp[-(R_{eq})^2 q^2/3]$ for each pseudocomponent, and frequently to assume that $2A_2 c \ll 1$ in an analysis used to estimate $(M_w)_0 \gamma$ and $[(R_{eq})_{LS}]_a$ for the assumed pseudocomponents as a function of the overall concentration $c$ (Guinier and Fournet, 24 p. 151). Similar treatments are applied with light scattering, often restricted to small enough $q$ that the expansion of $P_{Vv} (\theta, c)$ may be applied. The advent of dynamic light scattering has allowed some improvement in analyses of this type, since a similar expression (Equation 84) for the dynamic scattering can be applied in terms of pseudocomponents (see Equation 52):

$g^{(1)} (\tau, \theta, c) \approx \sum_{\mu} r_{\mu} (\theta, c) \exp[-\tau \gamma_{\mu} (\theta, c)]$

(84)

where $r_{\mu} (\theta, c) = [R_{Vv} (\theta, c)]_\mu / R_{Vv} (\theta, c)$. Analysis of $g^{(1)} (\tau, \theta, c)$ then provides information on $(M_w)_0 \gamma$ and a hydrodynamic length $[a_{LS}]_\mu = kTq^2/6\pi \eta \gamma_{\mu} (\theta, c)$ for...
each component, and some degree of consistency is expected among the estimates for \( (M_w)_0 \) obtained in the two experiments. Further, comparison of \([a_{LS}]_0\) and \([Rc]_0\) can provide insight into the nature of the component. In some cases, it may be reasonable to estimate \( (M_w)_0 \) for the component with smallest \( (M_w)_0 \) with the assumption that \( w_0 \approx 1 \) for that component, i.e., the scattering at small \( q \) reflects a small fraction of a large component. An example of a treatment of this kind may be found in Elnaga and Berry.\(^{145} \) In some cases, the depolarized scattering can be particularly useful if the association induces order in the aggregated species.\(^{146,147} \)

4.5 Scattering with Charged Species

In some cases, the polymeric and colloidal scattering species may bear electric charge. Whereas synthetic polyelectrolytes usually bear either anionic or cationic charge, biological macromolecules are often amphoteric, with a chain bearing both positive and negative charges. Electrostatic interactions among the scatterers may have two effects on macromolecules: (i) they may cause an expansion of the chain dimensions of macromolecules by intramolecular interactions, and (ii) they may alter the scattering through the effects of intermolecular interactions. Only the latter effect is relevant to charged particles. In the extreme, these interactions may lead to interactions with a very long coherence length, making it impossible to apply the relations discussed above.\(^{164} \) Fortunately, for the purposes of size characterization, the effects of electrostatic interactions on \( R_V(\theta, c) \) and \( R_B(\theta, c) \) may be suppressed or screened by the presence of simple electrolyte in the solution, thereby permitting application of the relations presented above, with one stipulation: the refractive index increment \((dn/dc)_T\) must be determined for the solution in osmotic equilibrium with the solvent containing the supporting electrolyte.\(^{164,184} \) Measurement of \((dn/dc)_T\) can be achieved by equilibrating the solution with the mixed solvent through a membrane of the kind used in measurements of the same pressure. The same procedure must be made with any mixed solvent with components of different refractive index, e.g., a mixed solvent comprising two organic liquids.

The Debye electrostatic length \( \kappa^{-1} \) provides an important measure of the spatial range of electrostatic interactions, with electrostatic interactions being suppressed between charged species that are much further apart than distance \( \kappa^{-1} \). Here (in the electrostatic unit system most often employed by physical chemists, Equation 85)

\[
\kappa = \sqrt{(8\pi N_A L_B I_0)^{1/2}}
\]

where \( I_0 = \frac{z_m^2 e_0}{42} \) is the ionic strength derived from small molecule ions in the solution, \( m \) being the molar concentration of species \( \mu \) with charge \( z_\mu \), and \( L_B = e^2/\kappa kT \) the Bjerrum length, with \( \kappa \) the dielectric constant (relative permittivity) of the solvent and \( e \) the charge on an electron. (It should be noted that variations of this expression with a factor \( 4\pi \varepsilon_0 \) multiplying \( \kappa \) appear if SI units are employed, with \( \varepsilon_0 \) the permittivity of free space). Thus, at \( 25^\circ C, L_B/\text{nm} \approx 57/\varepsilon \) and \( \kappa^{-1}/\text{nm} \approx (4.57\pi N_A \frac{z_m^2 m_\mu}{e})^{-1/2} \), or \( L_B \approx 0.7 \text{ nm} \) and \( \kappa^{-1}/\text{nm} \approx 0.42/ \bar{m}_\mu/\text{mol L}^{-1} \) for an aqueous solution of univalent charged simple electrolyte at \( 25^\circ C \).

With polyelectrolyte macromolecules, it is often convenient to adjust the supporting electrolyte composition to a level such that \( \kappa^{-1} \) is comparable to the geometric dimensions of a chain element. In this case, the thermodynamic diameter \( d_{\text{thermo}} \) appearing, for example in expressions for \( A_2 \), will not be dominated by the electrostatic interactions among chains, and the effects of intramolecular electrostatic interactions on the chain dimensions will be largely suppressed.\(^{16,32,51,148} \) If this is not done, reliable extrapolation of \( Kc/R(\theta, \varepsilon) \) to infinite dilution may be impossible if \( \kappa^{-1} > (M/\text{cN})^{1/3} \), an example of this effect for a rod-like chain is shown in Figure 13(a).\(^{149} \) A similar effect will obtain with charged particles in solutions, e.g., as is well known, interparticle electrostatic repulsion among spheres can be strong enough to lead to an ordered mesophase with increasing \( c \) if the average separation of the spheres is less than \( \kappa^{-1} \).\(^{150} \) In addition, for macromolecules, the chain dimensions may expand with increasing \( \kappa^{-1} \) if \( \kappa^{-1} > d_{\text{geo}} \), where \( d_{\text{geo}} \) is the geometric diameter of the chain repeat unit; an example of this is shown in Figure 13(b).

It should be realized that an aqueous solution of an organic solute is often close to intermolecular association, and that the addition of salt and consequent suppression of electrostatic interactions may induce association. Thus, with amphoteric proteins, it is often found that association will occur if the pH is adjusted to the isoelectric point, a condition for which appreciable numbers of anionic and cationic sites coexist on the chain.\(^{164} \) For a pH far from the isoelectric point, the amphoteric macromolecule behaves as either an anionic or a cationic polyelectrolyte and the net charge can help stabilize the solution against association.

The effects of electrostatic interactions between charged spheres dispersed in a medium of low ionic strength can lead to a striking effect on \( R_{\text{iso}}(\theta, c)/KMc \), resulting from large values of \( c \Gamma_{\text{iso}}(c) \) from electrostatic repulsion between the spheres. Thus, in this regime, Equation (86)

\[
\frac{R_{\text{iso}}(\theta, c)}{KMc} \approx \frac{P_{\text{iso}}(\theta, c)}{1 + c \Gamma_{\text{iso}}(c) F_{\text{iso}}(\theta, c) H_{\text{iso}}(\theta, c)^{-1}} \approx (c \Gamma_{\text{iso}}(c) H_{\text{iso}}(\theta, c)^{-1})^{-1}
\]
Figure 13 Scattering from a semiflexible polyelectrolyte chain in solvents with low and high ionic strengths (open and solid circles respectively). (a) $10^3[Kc/R_{vv}(0, c)]$ versus concentration $c$; the dashed line is to emphasize the extreme nonlinear behavior for the case with a low ionic strength. (b) $10^6[Kc/R_{vv}(\theta, c)]$ versus $\sin^2(\theta/2)$. (Adapted from figures in Sullivan and Berry).\(^{199}\)

where $H_{iso}(\theta, c)^{-1}$ is expected to exhibit a maximum associated with the distance of average closest approach of the spheres, e.g. the expression for $H_{iso}(\theta, c)$ given above for uncharged spheres. Data on several dilute dispersions of charged polystyrene spheres ($R = 45$ nm) are given in Figure 14.\(^{151}\) Similar results are reported for solutions of polyelectrolytes and for other charged particles.\(^{148}\) As mentioned above, these curves bear a qualitative similarity to those obtaining for coated spheres under some conditions with the zero average refractive index increment, but their origin is very different, as is their shape in detail. A first-approximation to $H_{iso}(\theta, c)$ might be obtained by using $\sin(\theta/2) \approx (2L_\kappa/R)\sin(\theta/2)$ in the expression for hard spheres if $L_\kappa \gg R$, where $L_\kappa$ is an electrostatic length, expected to be related to $\kappa^{-1}$.\(^{148,152}\) This approximation gives far too sharp a maximum, and values of $L_\kappa$ to match the position of the maximum that are far larger than $\kappa^{-1}$.\(^{151}\) In addition to the weakness of the ad hoc model, at least a part of this discrepancy may reflect heterogeneity or fluctuation of the charge density, which may broaden the peak.

Figure 14 Dependence of the structure factor on $qR$ for polystyrene spheres ($R = 45$ nm) immersed in deionized water, with the number concentration $c = 2.53$, $5.06$, $7.59$ and $10.12$ particles $\mu$m$^{-3}$ for the circles with increasing depth of the shading, respectively. (Adapted from figures in Grüner and Lehman).\(^{151}\)

4.6 Scattering from Optically Anisotropic Solute

Although the (excess) scattering from polymer solutions is usually too small to be of much interest, exceptions can arise for chains with a semiflexible, or rod-like, conformation, and with spheres comprising optically anisotropic scattering elements. It is often assumed that the refractive index tensor of the scattering elements has cylindrical symmetry, with refractive index $n_1$ and $n_\perp$ parallel and perpendicular to the cylinder axis, respectively.\(^{10,49}\) For this model, the orientationally averaged refractive index is $\bar{n}_{solute} = (n_1 + 2n_\perp)/3$, $\psi_{solute} \approx (\bar{n}_{solute} - n_{medium})/\rho_{solute}$, and $\gamma_{solute} \approx (n_1 - n_\perp)/\rho_{solute}$, with $\rho_{solute}$ the density of the solute (see Equation 9). If $\psi_{solute} \neq 0$, it is convenient to define the optical anisotropy of the scattering element as $\delta_0 = \psi_{solute}/\psi_{solute}$.

A macromolecular model of interest is that of the persistent, or worm-like chain of contour length $L$ and persistence length $\tilde{a}$, with a cylindrical polarizability tensor for the scattering elements, each having an optical anisotropy $\delta_0$. For this model, the mean-squared molecular anisotropy form factor is given by Equation (87),

$$\langle \delta/\delta_0 \rangle^2 = \frac{2}{3Z} \{1 - (3Z)^{-1}[1 - \exp(-3Z)]\} \quad (87)$$

where $Z = L/\tilde{a}$; the corresponding expression for $R_C^2$ is given in Table 2. In the limit where $\tilde{a} \ll L$, as for a flexible chain polymer (e.g. vinyl polymers and most
may be of interest itself to evaluate
dof a comparison of an estimation of the persistence length. An example
calculations in the RGD regime as a function of arising from helical structure,
where first maxima and following minima may be used to estimate
chain contour length. As a consequence such chains, and may be neglected when considering
a rod-like chain, is much smaller than \( R_{Vv}(0, c) \) for such chains, and may be neglected when considering
\( R_{Vv}(0, c) \). In the opposite extreme where \( L \ll \hat{a} \), as for a rod-like chain, \( \delta \approx \delta_0 \), and the anisotropic scattering
must be taken into account to determine \( M_w \) from \( R_{Vv}(0, c) \). For chains with an overall rod-like character arising from helical structure, \( \delta_0 \) may be so small that the anisotropic scattering may still be ignored when determining \( M_w \) from \( R_{Vv}(0, c) \). Nevertheless, \( R_{Vv}(0, c) \) may be of interest itself to evaluate \( \delta^2 \) for use in an estimation of the persistence length. An example of a comparison of \( \delta^2 \) as a function of \( L \) used to estimate \( \delta_0^2 \) and \( \hat{a} \) for a rod-like polymer is given in Figure 15.

As mentioned above, \( P_{Vv}(\theta, \pi/4, 0) \) exhibits extrema as a function of \( qR \) for monodisperse spheres, for calculations in the RGD regime and in the anomalous diffraction approximation, the values of \( qR \) for these first maxima and following minima may be used to estimate \( R \). In addition, the effects on the scattering pattern of the distortion of the anisotropic sphere, as might occur under a deformation, have been studied, see for example the discussion and literature citations in Samuels.

**Figure 15** Dependence of \( (R_{Vv}^2)_{LS} \) and \( (\delta/\delta_0^2)_{LS} \) on the ratio of the weight-average contour length to the persistence length for rod-like molecules with a distribution of contour lengths in parts (a) and (b) respectively. (Adapted from figures in Berry.)

**LIST OF SYMBOLS**

- \( \hat{a} \): Persistence length for semiflexible chains
- \( A_2, A_3 \): Second virial coefficient third virial coefficient, etc.; see Equation (8)
- \( b(c) \): Correlation length obtained from the dependence of \( R_{Vv}(\theta) \) on \( \theta \); see Equation (63)
- \( c, c_\mu \): Solute concentration (wt/vol); concentration of solute component \( \mu \)
- \( F_{iso}(\theta, c) \): Intermolecular structure factor \( R_{iso}(\theta, c)/KcMP_{iso}(\theta, c) \); see Equation (4)
- \( g^{(1)}(\tau, \theta, c) \): Normalized electric field autocorrelation function, \( g^{(1)}(\tau, \theta) \); see Equation (52)
- \( H_{iso}(\theta, c) \): Function \( \{F_{iso}(\theta, c)P_{iso}(\theta, c)\}^{-1} \); see Equation (6)
- \( k \): Boltzmann’s constant
- \( K \): Optical constant relating intensities to the Rayleigh ratio
- \( L \): Chain contour length
- \( LS \): Subscript to indicate the average of a function or parameter obtained in light scattering
- \( M \): Molecular weight
- \( M_L \): Mass per unit length, \( M/L \)
- \( n_\text{medium} \): Refractive index of the medium
- \( n_\text{solute} \): Refractive index of the solute
- \( n_\mu \): Number fraction of solute component \( \mu \)
- \( \eta \): Ratio \( n_\text{solute}/n_\text{medium} \)
- \( N_A \): Avogadro’s constant
- \( P_{iso}(\theta, c) \): Intramolecular structure factor; see Equation (4)
- \( P_{Vv}(\theta, c) \): Intramolecular structure factor for the horizontally polarized component of the scattering with vertically polarized incident light
- \( P_{Vv}(\theta, c) \): Intramolecular structure factor for the vertically polarized component of the scattering with vertically polarized incident light
- \( q \): The modulus \( q = (4\pi/\lambda) \sin(\theta/2) \) wave vector for an isotropic medium
- \( R_{aniso}(\theta, c) \): Anisotropic component of \( R(\theta, c) \)
- \( R_{iso}(\theta, c) \): Isotropic component of \( R(\theta, c) \)
- \( R_{Vv}(\theta, c) \): Horizontally polarized component of \( R(\theta, c) \) for vertically polarized incident light
- \( R_{Vv}(\theta, c) \): Vertically polarized component of \( R(\theta, c) \) for vertically polarized incident light

## 1 Introduction

This discussion of optical particle counting (OPC) points out application areas where the procedure is used to collect data that would not be available otherwise. These areas include determination of particle size distributions from the size data of individual particles, identification of particles that do not fit within a specified size distribution function, and characterizing the particles present in a process of product fluid. The designs, performance, and operation of OPCs for both gasborne and liquidborne particles are discussed. Capabilities and limitations in terms of particle size ranges, counting accuracy, concentration, and so on are pointed out. The primary limitation is related to the fact that OPCs respond not only to the size of the particles, but also to the optical nature of the particles and of the fluid. Data are also affected by the counter design. All respond to a physical and/or chemical property of the particles, as well as to their physical size and morphology. The limitations of OPCs in relation to those factors are considered.

Operational requirements for OPC are pointed out. These include good sample acquisition and handling procedures, consideration of the effects of differences between particle counter designs on reported data, requirements for careful calibration before use and the effects of differences between calibration particles and sampled particles. A brief summary of present national and international standard documents for calibration and operation of these instruments is included. Performance capabilities of current OPCs are summarized and possible future developments are discussed. Performance is considered in comparison with that of other particle measuring procedures.

out; effects of incorrect procedures are discussed. Calibration procedures and calibration materials are considered as they affect response and differences in response for instruments with design differences. The effects of such design differences are discussed. National and international procedure documents for calibration and operation of OPCs are summarized. Performance capabilities of present day instruments and possible future developments are summarized.

2 HISTORY

The first OPCs were modeled after optical devices developed for detection of airborne chemical and biological warfare agents in the late 1940s. These were based on light scattering systems used for testing high efficiency air filters. A laboratory instrument was produced for the US army and was modified for field use in 1954.(1) At that time, the airborne particle counter was capable of measuring particles in the “diameter” size range of 0.5–20 µm in concentrations up to approximately 3.5 × 10⁶ m⁻³. In 1965, a light extinction counter was developed for measurement of contaminant particles in hydraulic fluids, fuels, mineral oils, and other lubricants. The liquidborne particle counter could measure particles in sizes from 5 to 200 µm in concentrations up to approximately 3.5 × 10⁵ m⁻³.² Sensitivities and concentration capabilities have increased significantly for present day instruments and will probably continue to increase in the future. At the same time, the overall bulk and weight of instruments continues to decrease, while new electronic component developments permit more data acquisition, storage, and processing.

3 APPLICATION AREAS

3.1 Determination of Product or Process Particle Size and Quantity

Production and processing of a wide variety of materials are affected by the physical and chemical properties of finely divided materials that are either used in the production operation or are the end product. For example, reaction rates are affected by the available surface area of process materials. Reaction time requirements can be reduced by extending the reactant powder surface by reducing particle size. In handling bulk powders, power requirements to maintain flow through ducts can be reduced by including a range of particle sizes rather than using a single size batch of materials. Process effluents, when exhausted through a stack or in a gas stream, are often controlled by ordinances that specify allowable effluent opacity. The particle size of the material in that effluent will materially affect the visibility of the exhaust plume. This is due to the sensitivity to particle size of the extinction coefficient when particle size approaches the wavelength of visible light.

Many pharmaceutical products are applied by injection of a solids suspension in liquid or by the inhalation of aerosolized dry or liquid particles. The deposition location of such materials is frequently controlled by particle size. Correct operation of much material processing equipment includes verification that the product material particle size is within the specified size range limits. Particle size control may involve dry particle comminution or agglomeration or control of liquid droplet size. Essentially all of the particle size measurement in these application areas can be made either during or after production, using OPCs.

When the required information on particle size and/or quantity is only restricted to the mass or volume of particulate material or to the particle size distribution, OPC may not be the best method to obtain such information. Scattered light measurement of an array of particles, rather than of individual particles, can provide particle size distribution parameters directly. Collection and weighing a sample of the particles can provide particle mass data. However, when information is needed on whether or not all particles in the material being measured fit within the required size distribution limits, single particle sizing and counting by an OPC is frequently the only on-line method that can be used.

3.2 Determination of Fluid Cleanliness or Contamination Level

Ambient atmosphere contamination conditions are of importance in many production areas. Particulate air pollution in residential areas has been a concern for many years, but typical measurement methods did not involve detailed measurement of particle size. Environmental air pollution data for particulate materials has been based on either visibility of emission sources or on mass per unit volume of ambient air. During the 1990s, ambient air pollution in the USA became concerned with control of particles in the respirable size range. Specifications for concentrations of particles ≥2.5 µm and ≥10 µm are appearing. Further consideration of the physical and chemical effects of particles that are deposited and retained in the lungs can be expected. At this time, the procedures for measuring airborne particulate air pollution still require data in the form of particle mass per unit volume of sampled air. Measurement of particles by filtering an air sample and weighing the collected particles is now in use and is quite effective for particles larger than approximately 5 µm in diameter. However, the smaller particles require much larger air sample volumes.
measurements can be made on a continuous basis or at component or from a potential contamination source. OPC is used to observe fluid flow towards an in-process not affected by contamination generation incidents. An cleanliness, has been used to verify that product quality is the 1980s, continuous monitoring of a process or facility characterization of the particles in the total flow. ensure that the sample portion is sufficient to permit valid measurements within production tools during critical pro-

2 In situ sample, consisting of a portion of the fluid flowing contained within the transparent tubing, but the optical and electronic systems are essentially identical to those for the airborne particle counters. There is one other difference between some specified time intervals. Procedures for measurement at a large number of sample points can be established. These procedures can use a single particle counter that receives sequential samples from a series of sample collection points. Each selected sample point feeds fluid into a line that is connected to a central source selection controller that sequentially selects one of the lines and feeds sample to the particle counter for a preselected time interval. The particle counter electronic system and/or external control system can report particle concentration for each of the selected sample points. Data from these measurements can be used to verify that the sample point or an area containing many sample points is in compliance with a fluid cleanliness specification.

4 OPERATING PRINCIPLES OF OPTICAL PARTICLE COUNTERS

4.1 Light Scattering Optical Particle Counters

The basic operation of a light scattering particle counter is shown in Figure 1. The operational part of the counter contains a light source, an optical system for beam shaping to define a sample view volume, a light collection optical system consisting of either lenses or mirrors to collect the scattered light, a photodetector that will convert optical signals to electrical signals, and a signal processing electronic system to convert the electrical signals to information on the size and number of detected particles. Ancillary flow control systems are required to handle the sampled fluid. Light scattering particle counters for liquidborne particles contain the fluid sample stream in transparent tubing, but the optical and electronic systems are essentially identical to those for the airborne particle counters. In a similar development that became important during the 1980s, continuous monitoring of a process or facility cleanliness, has been used to verify that product quality is not affected by contamination generation incidents. An OPC is used to observe fluid flow towards an in-process component or from a potential contamination source. Measurements can be made on a continuous basis or at

Because of their much smaller mass. For this reason, OPCs can generate useful data much faster than the particle collection and weighing method.

In the industries producing electronic, pharmaceutical, optical, and precise mechanical components, the clean-

room production facilities require control of airborne particles to levels where no more than a specified num-
ber of submicrometer particles per unit volume of air can be present. Some semiconductor facilities allow no more than ten particles $\geq 0.1 \mu m$ per cubic meter of air. Deionized water used for cleaning during production is filtered to cleanliness levels of no more than ten particles with diameter $\geq 0.05 \mu m$ per liter of water. There are no formal specifications for these levels, but production history dictates such cleanliness requirements. That same history indicates that even cleaner production facilities will be required in the future. For operation of precise mechanical or hydraulic control systems, the fluid cleanliness requirements are also based on operational history. The cleanliness level requirements for those fluids are several orders of magnitude less severe than required by the semiconductor industry. In pharmaceutical and medical device production, the Food and Drug Administration (FDA) in the USA and similar agencies in other countries require that both air and water used in production be controlled to appropriate particulate cleanliness levels.

As a result of constant changes in product performance requirements in the semiconductor industry, the need to monitor continuously the cleanliness of the process fluids and of the air environment has resulted in development of some new OPC systems. These devices are used for in situ measurements within production tools during critical production stages. These in situ counters observe the cleanliness of the gases and liquids during such actions as chemical vapor deposition system pressure adjustments, operations, and movement of product elements prior to, during, and following those operations. These gasborne particle counters may be required to operate under extreme temperature and pressure conditions. In some cases, the particle counter sensing element is contained within the tool so that gas flow passes through that element. In other cases, the element is contained within a flow line containing fluids either to or from a process action. An in situ sample, consisting of a portion of the fluid flowing through that line may be measured. Care is required to ensure that the sample portion is sufficient to permit valid characterization of the particles in the total flow.

In a similar development that became important during the 1980s, continuous monitoring of a process or facility cleanliness, has been used to verify that product quality is not affected by contamination generation incidents. An OPC is used to observe fluid flow towards an in-process component or from a potential contamination source. Measurements can be made on a continuous basis or at

![Figure 1](https://example.com/figure1.png)
PARTICLE SIZE ANALYSIS

airborne particle counters and the liquidborne particle counters. As will be seen later, the capability to detect very small particles increases as the illumination source intensity increases. When a gas laser is used as the light source, the beam intensity in the view volume is normally a very small fraction of the intensity of the beam present in the active cavity between the two mirrors where the gas is located. By replacing one of the containment mirrors with a Brewster’s angle window, one of the mirrors can be moved sufficiently far from that panel that a space large enough to pass a gas stream containing the particles to be measured can be exposed to the very high light level present within the active cavity of the laser. This cannot be done when the fluid being sampled is a liquid. The refractive index of the liquid differs sufficiently from that of the gas in the laser and in the external active cavity so that insertion of the liquid degrades the beam in the “external” active cavity to the point where signals from particles are decreased significantly. Use of a solid-state diode laser that can emit light at high levels is used when very small particles (≤0.1 µm) in liquid are to be measured.

When no particles are in the sensing volume, only the near-constant level light scattered by fluid molecules enters the collection optical system; the signal output from that source is below the signal level for particle data. As particles pass through the sensing volume, scattered light pulses are generated by each particle. The scattered light pulse pattern depends on the particle size and the ratio of the refractive index of the particle and of the substrate fluid. The refractive index ratio is shown in Equation (1)

\[ m = \frac{n_p - ik_p}{n_m} \]  

where \( m \) is the refractive index ratio, \( n_p \) is the real part of the particle refractive index, \( ik_p \) is the imaginary (absorption) part of the particle refractive index, and \( n_m \) is the refractive index of the fluid medium in which the particle is suspended.

Figure 2 illustrates scattering patterns for particles in several size ranges. The photodetector collects each light pulse that is scattered over the angle in which the collection optical system is operating. The photodetector

![Figure 2](image)

converts the light flux to an electrical signal and feeds that signal to the electronic system of the particle counter. Each pulse amplitude is measured and the pulses within defined amplitude ranges are counted. Pulse amplitude varies as a function of particle size. Since the sampled fluid flow rate is controlled, particle concentration in each size range can be determined.

Operation of the light scattering particle counter is neither as simple as the quick summary above may indicate, nor is it as complicated as might be expected from light scattering theory. Light scattering theory is complex. However, there are some fundamental parameters that affect particle counter response. These include (1) configuration of the illumination and collecting optical systems, summarized as scattering angle; (2) light intensity and wavelength; (3) size of the particle in the sensing volume; (4) the particle refractive index relative to that of the surrounding fluid. The scattering angle controls the quantity of light collected for any particle. For a larger solid angle, more light will be collected. Care is needed in optical design, since counters with larger solid angle collection optical systems can also collect background light reflected from components in the optical system. That background light is essentially optical noise signals that result in false data.

The basic optical system designs used in every light scattering particle counter are shown in Figure 3. Minor differences exist in some instruments. For example, the right angle scattering optical system in the topmost design in Figure 3 has been modified to use a scattering angle base that is approximately 120°, rather than 90°. Dual detectors can be used to improve signal levels for better small particle measurement capability. The wide-angle collection system in the middle design uses a set of mirrors to collect the scattered light and to focus that light upon the photodetector.

The derivation of equations defining light scattering is available in the literature and will not be repeated here. Without going into detail, the important parameters that define scattering from a particle include the particle size, the refractive index ratio (including both real and imaginary components) of the particle and of the suspension medium, the illumination wavelength and the solid angle over which the light is collected. The theoretical relationship for light scattering by small particles is shown by Equations (2) and (3), the Rayleigh scattering equations for small particles. Equation (2), for perpendicularly polarized light, shows nearly equal scattering at all angles, while Equation (3), for parallel polarized light, shows scattering equal in intensity to that for perpendicular polarization at θ = 0 rad and θ = π rad, while decreasing to zero at θ = 0.5π rad, as shown for the scattering from a 0.15 µm particle in Figure 2.

\[ I_1 = \frac{\alpha^4}{2\pi} \left( \frac{m^2 - 1}{m^2 + 1} \right)^2 \]  

\[ I_2 = \frac{\alpha^4}{2\pi} \left( \frac{m^2 - 1}{m^2 + 1} \right)^2 \cos^2 \theta \]

where \( I_1 \) is the scattered light flux polarized perpendicularly to the incident light, \( I_2 \) is the scattered light flux polarized parallel to the incident light, \( \alpha \) is the particle circumference divided by the illumination wavelength, \( m \) is the particle refractive index, relative to that of the suspension medium, and \( \theta \) is the scattering angle with respect to the forward direction in degrees.

Scattering theory states that the scattered light signal is a function of the wavelength of the incident light on the particle, the state of polarization of that light, the scattering angle, the refractive index ratio of the particle and the substrate fluid, the particle size, shape, and orientation. Light scattering from particles with dimensions at and below the wavelength of the incident light is identified as Rayleigh scattering. The scattered light signal level is proportional to \( d^6/\lambda^4 \), where \( d \) is the particle diameter and \( \lambda \) is the wavelength of the incident light. A small change in particle size changes the scattered light signal significantly. Light scattering from particles with dimensions at and above the wavelength of the incident light is identified as Mie scattering. Figure 2 shows scattered light patterns from particles in both size ranges. Equation (4) is the Mie scattering equation describing scattering for particles of larger size.

---

**Figure 3** Optical systems for light scattering particle counters. (Adapted from J.R. Hodkinson, J.R. Greenfield, ‘Response Calculations for Light Scattering Aerosol Counters’, *Appl. Optics*, 4(11), 1463–1474 (1965).)
with vertically polarized light.

\[ I_1 = \sum_{m=1}^{\infty} \frac{2m+1}{m(m+1)} \left[ a_m \tau_m(\cos \theta) + b_m \tau_m(\cos \theta) \right]^2 \]  

where \( a_m \) and \( b_m \) are complex amplitude functions dependent on \( m \) and the particle diameter, and \( \tau_m \) are angular functions depending on \( \theta \).

If a well-collimated beam of light is passed through a fluid, any particle with a light extinction coefficient other than zero that is in the light path will remove light by a combination of scattering out of the direct beam and by absorption. If the absorption part of the particle refractive index \( (k_a) \) is zero, light is removed from the beam solely by scattering. The particle extinction coefficient defines the combined effects of scattering and absorption. Beer’s law, relating the transmitted and incident light flux, may be written as shown in Equation (5).

\[ I = \exp(-A_{cn}L) \]

where \( I \) is the ratio of light flux after interaction with the particle to incident light flux, \( A \) is the projected area of particle(s) illuminated by the incident light, \( c_n \) is the numerical particle concentration, and \( L \) is the beam pathlength through the effective sensing volume.

At this time, optical particle counters using scattered light signals for particle counting and sizing are in use with illumination sources using incandescent filaments, gas lasers, and solid state lasers. Incandescent filament sources (with their wide range of illumination wavelengths) are used mainly to reduce multivalue response effects. Laser sources are used for measuring particles significantly smaller than 1\( \mu \)m in diameter. HeNe laser sources (illumination wavelength of some 633 nm) are used in the active or passive cavity mode to permit passing the observed particles through the sensing volume where illumination flux is at a maximum. Argon ion lasers (illumination wavelength of some 400 nm) are used as illumination sources for work with particles somewhat smaller than 0.1\( \mu \)m in diameter. Solid-state laser sources (illumination wavelength in the range of 650–900 nm) are used as conventional illumination sources supplying high illumination levels. The small size and high reliability of high-power solid-state lasers, that operate without the need for high-voltage power supplies, has resulted in their increasingly widespread application. Particle counters using polychromatic light and large solid angle light collection systems produce the desired single-valued response, but sensitivity for small particle measurement is decreased and background noise must be minimized.

As of 1996, both airborne and liquidborne particles of 50\( \mu \)m and larger could be counted and sized efficiently. Most light scattering optical designs use wide-angle light collection systems to maximize particle sizing resolution capability and to minimize multivalued response where the signal both increases and decreases as measured particle size increases. Right angle optical systems are widely used with Mangin mirrors (concave spherical mirrors that can collect and focus light to the photodetector) collecting the light over a total angle of \( 90^\circ \pm 45^\circ \). This system is now used for counting and sizing particles in the size range from 50\( \mu \)m and larger. There are many optical designs used for particle counting and sizing instruments at this time. A more detailed discussion on design and operation of light scattering OPCs is given in a recent ISO (International Organization for Standardization) standard. This discussion also covers air flow system design and operation to ensure that the fluid sample stream is completely within the sensing zone so that all particles are adequately illuminated.

The variety of designs and components result in significant differences in response when different instruments are used to characterize the same particle samples. Data variability is reduced by the following procedures:

1. Minimize differences in the optical designs of the instruments used.
2. Calibrate all instruments, preferably with certified reference particles with traceable dimensions, with all instruments using the same calibration procedures and materials.
3. Do not use instruments beyond their capabilities of particle size range, fluid flow rate, or environmental conditions.

### 4.2 Light Extinction Optical Particle Counters

The optical systems used for light extinction particle counters illuminate a small volume of flowing fluid and characterize particle content of that fluid by the reduction in the amount of light passing through that volume due to the particle(s) within the flowing fluid. The light beam is directed to the photodetector element. The fluid stream flows through a region of uniform illumination. When there are no particles in the illuminated volume of fluid, a constant signal is received by the photodetector. As a particle passes through the sensing volume, some light is removed by the particle as a result of scattering out of the direct beam and/or by absorption by the particle. Thus, a signal proportional to a function of particle size is generated. For particles smaller than approximately 5\( \mu \)m, that signal varies with the refractive index of the particle. For larger particles the extinction coefficient stabilizes at a value of two, regardless of the refractive index of the particle. For this reason, differences in optical properties of the calibration particles and
the measured particles do not produce as great signal differences as occur for particles smaller than 5 µm. The scattering coefficient is strongly dependent on the particle/fluid refractive index ratio, especially for particles smaller than 5 µm in diameter. These instruments are used mainly for measurement of particles suspended in liquid. Some extinction instruments are also used for sizing and counting dry particles that are large enough so that they can be passed through the sensing volume by dropping them from a vibratory feeder and allowing gravity to move them through the light beam at a velocity sufficient to keep the residence time to no more than 50 µs or so. Figure 4 shows the optical system for an extinction optical counter that observes the full liquid sample stream. A transparent rectangular or circular flow tube defines the sensing volume cross-sectional area; the height of the sensing volume is defined by the configuration of the illumination beam. The beam height is normally a few tens of micrometers and the beam width extends across the full liquid sample stream; many systems have areas in the range of 0.5–1.0 cm².

![Figure 4](image)

**Figure 4** Optical systems for light extinction particle counter. (Reproduced by permission of Particle Measuring Systems, Inc.)

Essentially the same parameters affect the response of the OPC using light extinction as the counter using light scattering. The optical properties of the particle/fluid system affect the extinction system response markedly, particularly for small particles. This is due mainly to the fact that the refractive indices of many process and product liquids are frequently similar to the refractive index of the particles being measured. However, as the measured particle size increases above 5 µm, the extinction coefficient stabilizes at a value of 2.0 for essentially all refractive indices, reducing that cause of error. This effect is shown in Figure 5.\(^{(6)}\) The projected area of the particle affects the amount of light removed from the direct beam and its orientation as it passes through the sensing volume in a manner similar to the effects pointed out for light scattering systems. The response curve for the extinction optical counter is a power function that varies from approximately the fourth power of particle size for particles in the micrometer size range and decreases to approximately the second power for particles larger than approximately 5 µm in diameter. Most light extinction OPCs use an optical system that observes light that is nearly a totally parallel beam. The beam intensity through the sensing volume is close to uniform, with minimum differences due to the normally Gaussian intensity distribution in a laser beam or the intensity variations from a ribbon filament incandescent light source. For this reason, particle sizing resolution for light extinction OPCs is excellent unless assembly or alignment problems cause excessive variation of light intensity in the sensing volume. This characteristic of extinction systems improves data reliability, particularly when measuring particles with wide variations in shape factor or composition.

![Figure 5](image)

**Figure 5** Theoretical and experimental light extinction coefficients. (a) Mie theory, (b) measured data. (Adapted from J.R. Hodkinson, ‘The Optical Measurement of Aerosols’, in *Aerosol Science*, ed. C.N. Davies, Academic Press, New York, 1966.\(^{(6)}\))

5.1 Sample Fluid Flow Rate
Since much of the data desired from OPC applications involves particle concentrations, accurate sampled fluid
flow rate data are a requirement. Specifications for such data require measurement of fluid flow with an external flow-measuring device that will not generate excessive pressure drop for gasborne particle counters. For liquidborne particle counters, a flow measuring device that can be operated to avoid indication of multiphase (gas and liquid) fluids as single phase fluids is necessary.

5.2 Background Noise Count Rate
When seeking maximum size sensitivity, OPCs may be operated with electronic systems set at maximum gain. In this situation, random electronic or optical noise may generate pulses large enough so that they can be reported as signals from small particles. In this case, erroneous data are generated that indicate more particles than are actually present in the measured sample. Operating the particle counter with particle-free fluid entering the sensing volume can identify this situation. Use of a filter with pore size no more than half the size of the smallest measurable particle on the fluid flow line can satisfy this requirement. The counter can be operated in this manner for time periods up to 30 min for two or three measurements and the observed noise count rate can be stated.

5.3 Particle Sizing Accuracy and Size Measurement Range
The need for sufficient data to provide statistical validity in characterizing particles has resulted in development of particle counters that can count and size particles of the smallest possible size with good accuracy and can portray the size distribution over as much as possible of the actual size range of the sample being measured. For light scattering particle counters used for either gasborne or liquidborne particles, size measurement of 0.05-µm particles is possible with several commercially available instruments. It is possible to obtain size data up to as much as 100 times the smallest possible size measurement. For light extinction OPCs, calibration particles ≥1 µm can be measured. The other end of the dynamic range capability is at 100 times the smallest size. The particle sizing accuracy should be no less than 95%. These data are based on the modal diameter stated for a batch of calibration particles that have been measured by an accepted particle sizing procedure.

5.4 Particle Size Resolution
Size resolution is the capability to differentiate between particles of nearly the same size. Accepted sizing resolution is the ability to differentiate between particles that differ by more than 5% in diameter. This value is determined by measuring a batch of near-monodisperse calibration particles that have been measured by a reference method that has provided data on the modal size and the relative standard deviation of sizes. The reported relative standard deviation should be no more than 5% greater than the specified standard deviation from the reference method data.

5.5 Particle Counting Accuracy
Although particle counting accuracy is considered a requirement mainly for determination of particle concentration when the quantity of particles is of concern, this is also a problem when establishing particle size distribution if any of the size ranges being measured do not report the particle population accurately. The particle counting accuracy is verified by counting aliquot samples of a particle suspension by the particle counter under test and by a referee method. The referee method can be an instrument other than the OPC or it can be an OPC that has been verified as producing accurate particle count data over the size range of concern. Counting accuracy requirements are typically stated as 50% ± 5% at the most sensitive size capability and 100% ± 5% for all particle sizes at least 1.5 times larger than that most sensitive size.

5.6 Particle Concentration Limits
The maximum concentration that can be accurately measured by any particle counter is limited by the accepted coincidence error. This error is due to the probability that more than one particle is present in the sensing volume at any time. The error level is a function of the physical dimensions of the sensing volume, the actual particle concentration within the sample being measured, and the particle size distribution of the particles in that sample. For samples where all particles are so small as to be insignificant in dimensions in comparison to

![Figure 6 Coincidence effect on reported concentration accuracy. (Adapted from A. Lieberman, Contamination Control and Cleanrooms: Problems, Engineering Solutions, and Applications, Van Nostrand Reinhold, New York, 357, 1992.)](image-url)
those of the sensing volume, the probability of more than one particle being present within a defined volume can be calculated directly from statistical theory, as shown in Figure 6. Figure 6 shows the ratio of reported concentrations to true concentrations for two optical liquidborne particle counters; one had a rated concentration capability of 12 000 particles per mL and the other a capability of 3000 particles per mL. However, the electronic circuitry in any particle counter cannot respond to the presence of a particle entering the sensing volume until the signal from a previous particle in the sensing volume has decreased to the system reset level. When particles are so large that their size is significant in comparison with a sensing volume dimension, the presence of such a particle causes an effective increase in the sensing volume dimension, as shown in Figure 7. The presence of large particles in the sample decreases the reported particle concentration limit more than expected from the calculation of the probability of coincident small particles in the sensing volume alone.

5.7 Instrument Stability and Verification

This all-inclusive performance requirement is handled by ensuring that the calibration procedure fits the application requirements and that calibration is carried out at no more than the maximum time interval specified for the particle counter in use or the regulatory document specified for the application where the measurements are being made. Details of calibration procedures are provided below where a summary of some national and international standard documents and their sources are summarized. Not all of the existing standard documents are included, but those indicated cover essentially all of the information required to carry out the procedures and operations that will aid in generating valid data for particle counting.

6 STANDARD DOCUMENTS FOR PERFORMANCE AND OPERATION

6.1 Gasborne Particle Counter Performance Documents

1. ASTM F328: Determining Counting and Sizing Accuracy of an Airborne Particle Counter Using Near-monomodisperse Spherical Particles (ASTM, American Society for Testing and Materials)
5. JIS B9921: Light Scattering Automatic Particle Counter (JIS, Japanese Industrial Standards)

6.2 Gasborne Particle Counter Operation Documents

1. ASTM F50: Continuous Sizing and Counting of Airborne Particles in Dust-controlled Areas and Clean Rooms Using Instruments Capable of Detecting Single Submicrometer and Larger Particles (ASTM)
2. BS 5295(4): Environmental Cleanliness in Enclosed Spaces. 4. Specification for Monitoring Clean Rooms and Clean Air Devices to Prove Continued Compliance with BS 5295: Part 1 (BSI)
3. Federal Standard 209E: Airborne Particulate Cleanliness Classes in Cleanrooms and Clean Zones, Appendix B (IEST, Institute of Environmental Sciences and Technology)
4. ISO 14644-3: Cleanroom Measurements and Metrology (ISO)
5. JIS B9920: Measuring Methods for Airborne Particles in Clean Rooms and Evaluating Methods for Air Cleanliness of Clean Rooms (JIS)

6.3 Liquidborne Particle Counter Performance Documents

1. ASTM F658: Defining Size Calibration, Resolution, and Counting Accuracy of a Liquid-borne Particle Counter (ASTM)
2. ANSI/NFPA T2.9.6R2: NIST (National Institute of Standards and Technology) Traceable Calibration Method for Liquid Automatic Particle Counters (ANSI, American National Standards Institute)
3. DIN 50432: Part 2, Test Method for Particle Analysis in Liquids: Determination of Particles with Automatic Particle Counter (DIN, Deutsches Institut fur Normung)
4. JIS B 9925: Light Scattering Automatic Particle Counter for Liquid (JIS)

6.4 Liquidborne Particle Counter Operation Documents

1. JIS K 0554: Testing Method for Concentration of Fine Particles in Highly Purified Water (JIS)
2. SEMI C1-88: Calibration & Measurement Methods for Particles in Liquids (SEMI, Semiconductor Equipment Manufacturers International)
3. ANSI B93-73M: In-line Liquid Automatic Particle Counting Systems – Method of validation (ANSI)

7 OPERATIONAL REQUIREMENTS FOR PARTICLE COUNTING

7.1 Sample Acquisition, Handling, and Storage Requirements

Particle counting is used to carry out three types of particle measurement. The particle size and size distribution of samples from bulk powders are defined; the particulate content of ambient air or liquid is measured; the particulate content of process or product gas or liquid is measured. The three application areas have one common requirement that must be satisfied before any useful data can be collected. This is the requirement that a valid sample be acquired and that the sample be handled so that no data are collected that have been generated by improper sample handling procedures. The procedures and the reasons for these procedures will be discussed for the three application areas.

7.1.1 Bulk Powder Sampling Procedures

When particle counting is used to make measurements of bulk powders, the objective is to determine a particle size distribution and to define outlier particles that are either too small or too large to fit into the size distribution correctly. During transport or storage, the particles in the powder will frequently pack in such a way that portions of the powder bulk will contain particles with a size distribution that differs from the original distribution. As an example, vibration may cause small particles to settle through the interstices between large particles. Even so, it is still necessary to procure a representative sample of the total material. This may require special care in taking samples from a container where polydisperse material is stored. To sample correctly, an accepted procedure should be followed including subsample preparation via spinning riffler or other accepted powder subdivision procedure. This procedure may require more than one repetition to produce samples small enough for measurement by OPC. The sample is then dispersed into
the fluid in which it will be measured. It should be followed immediately by measurement of the particles suspended in that fluid. If samples are dispersed into liquid, stirring or agitation is required before measurement of the suspended particles is carried out. This dispersion should be carried out in such a way that a minimum quantity of air is aspirated into the suspension. If any gas is present, gas bubbles will form and may be interpreted as particles. Transport of fluid suspension in ducts or tubes should be carried out with tubing that does not contain any sharp bends or short radius elbows. These can cause deposition of particles due to centrifugal force during transit through the tubing. Excessive residence time (more than 3 min in gas or 5 min in liquid) in the tubing should be avoided. Large particles may be lost to tube walls via gravitational settling or turbulent flow impaction losses. Small particles may be lost via diffusion to the tubing walls or by agglomeration with other particles. Small dry powder samples can be stored in closed containers for long time periods with no significant changes in the samples. Powders dispersed in gas cannot be stored longer than a few minutes unless the particles are so small that diffusion by the gas molecules will keep the particles dispersed until size measurements are made. For particles in liquids, samples stored for more than 30 min or so will require stirring or agitation before particle size or concentration measurements are made unless no particles larger than 5 µm are in the powder.

7.1.2 Ambient Air Sampling Procedures

Ambient air sampling procedures are often specified by regional air pollution control agencies. Until the 1980–1990 period, the requirements for air pollution control of inert particulate materials were based only on mass loading of total airborne particles with no specifications as to the size of those particles. Most requirements for acceptable particulate levels in the ambient air are expressed in terms of milligrams per cubic meter. The particle population for those levels is beyond the detection capability of all but a few research type OPCs. In the late 1970s, information from industrial hygiene studies and research on particulate material retention in the respiratory tract generated concern about the particle size of inert airborne particles. From that time, the EPA (Environmental Protection Agency) in the USA, along with similar agencies in other countries, began specifying that data on the mass loading of particles ≥2.5 µm and ≥10 µm should be collected. For this reason, it can be expected that ambient air measurement using OPC and sizing may also become a requirement. These measurements will require sample acquisition procedures that collect particles with sizes ≥2.5 µm and ≥10 µm in such a way that the concentration of those particles can be defined correctly. Isokinetic sampling or an equivalent procedure will be required for airborne particles larger than approximately 5 µm. Sample storage for particles to be measured using an OPC is not anticipated. The optical system will be incorporated with the sampling system for immediate measurement with data either stored or transmitted electronically to a central data processing facility.

For air flow sampling isokinetic sampling is required for all particles larger than approximately 5 µm; for liquid flow sampling, isokinetic sampling is required for particles larger than approximately 10 µm. Isokinetic sampling requires that the sample probe inlet flow is at the same velocity as that of the sampled fluid flow. In areas where the sampled fluid flow rate may vary, then isoaxial sampling is recommended. In areas where sampled fluid flow direction and three-dimensional velocity may vary in a random manner, then a sample probe that faces upward is recommended so that “large” particles will be sampled with maximum accuracy. In essentially all areas where processor product fluid cleanliness data are of concern, the OPC has been widely used. In production areas for the electronics industry and the pharmaceutical industry, the standard procedures specify OPC instruments for particle size and concentration data production. For areas where particles smaller than 0.1 µm are of concern, scanning electron microscopy measurement of particles that have been collected from fluid samples is also used. However, the higher capital costs, labor time, and delay between sample acquisition and data availability connected with that method has resulted in use of OCs in many areas where measurement of particles ≥0.05 µm is required.

7.1.3 Process and Product Fluid Sampling Procedures

Many products presently in common use are based upon complex technological components. Most of the operating parts of computers, automobiles, communication systems, and optical devices are components that must be produced in clean areas where particulate contamination in the air in production areas would cause immediate or later failures. Pharmaceutical and other health care products such as injectable liquids and medical devices must be produced in areas where both viable and inert particle content of the environmental air and the process liquids are carefully controlled. Hydraulic fluid power control systems contain components with moving parts operating with very small clearances. Particulate contaminants in the hydraulic fluid must be controlled to minimize control action errors. Performance of optical components, such as high-accuracy mirrors, long-range lens systems, film for use in medical applications of electron microscopy, and so on, can be degraded if contaminant particles in micrometer sizes are deposited upon those critical surfaces.
during production. Most automobile painting facilities are now operating with ventilation air systems containing high-efficiency filters to prevent any atmospheric particulate debris from degrading those surfaces by deposition upon the still-wet paint. Air cleanliness is of paramount importance in essentially all areas where particle contaminants may degrade product quality. The facilities where particle-sensitive production occurs, known as “cleanrooms” are kept as clean as possible by controlling the ventilation air cleanliness with a filter which has a particle removal efficiency from 99.97% for particles $\geq 0.3\mu m$ (for routine operations) to removal efficiencies of 99.9999% for particles $\geq 0.1\mu m$ for semiconductor production. Unidirectional airflow moving at a velocity of $0.5 m s^{-1}$ is used in very clean areas. The concentration of particles $\geq 0.1\mu m$ in some work spaces is kept at levels of no more than $100 m^{-3}$. Air flow in the most sensitive areas is controlled so that air movement is unidirectional with minimum recirculation of potentially contaminated air in the cleanroom. The objective is to verify that the particle concentration in that air is less than $10\sim 100$ particles per cubic meter. Air sampling in critical areas is continuous, with particle counters sampling air at $0.47 m^3 s^{-1}$ and sizing and counting all particles $\geq 0.1\mu m$ in diameter. The particle counter sample line inlet faces into the air-flow path and the inlet velocity is controlled so that isokinetic sampling is assured. In areas where products are not as sensitive as the semiconductor products, the air flow direction and three-dimensional velocity may be random; a sample probe that faces upward is recommended so that “large” (>5 µm) particles will be sampled with minimum loss. If the particle counter is not located directly in the sampled air flow, a sample probe may be located at the end of a sample transport tube. Experience has shown that residence time in the tube must be minimized and that turbulent flow is desired to minimize gravitational losses. For valid measurement of particles smaller than 2 µm, tubing lengths up to 30 m can be used with the Reynolds number for the gas flow maintained between 5000 and 25000. For valid measurement of particles of 5 µm and larger, tubing lengths should not exceed 2 m. The same limitations on the Reynolds number for air flow apply for the larger particles. These limitations ensure that laminar air flow is not present in the tubes and that turbulence is not so great that excessive particle impaction occurs upon the tubing walls.

When product or process liquids are to be examined for particle content, the sampled liquid will be in a process or product flow line or batch samples already in containers will be examined. Acquisition of samples from a line containing flowing liquid requires that two factors be considered. First, it is necessary that samples be procured from a line that is completely filled with liquid. Sampling from zones of mixed gas and liquid should be avoided. The bubble content of liquid from such areas cannot be anticipated and the quantity of liquid removed for each sample is difficult to measure with any accuracy. The second requirement is that the sample should be removed so that the removal does not cause loss of any particles due to centrifugal force produced by excessive curvature of the sample flow path. When process or product liquids are to be measured for particle content, the sampled liquid will either be in a flow line, or batch samples will be examined. Acquisition of samples from a flowing line requires that a sample probe line be inserted into the sampled line. The sample probe line should not be configured so that the sampled liquid is moved through a short radius-of-curvature elbow or a line that imposes centrifugal force upon the particles in the sampled liquid. Figure 8 illustrates two recommended configurations and one less desirable configuration for liquid flow line sampling. The same configuration should be considered for possible use in gas flow sampling from lines where high velocity or high pressure gas is to be sampled. As previously mentioned, sampling for measurement of large particles is best accomplished with isokinetic sample flow control. After a flow line sample has been passed through the sensing volume of the OPC, disposal or return of the measured sample to the process line may be required. Care is required in disposal of liquids that may be hazardous. Consideration of the Material Safety Data Sheet (MSDS) requirements for handling as well as local and other municipal safety requirements in

![Figure 8](source)
handling process and product liquids must be part of the sample handling and disposal protocol.

If batch samples are to be measured, these samples should be in containers that can be placed in a sample feeder attached or attachable to the OPC. Use of “round-bottom” sample containers is suggested, whenever possible, so that any necessary stirring does not result in particles being deposited upon vertical container walls. Before samples are measured, the sample container should be shaken, or otherwise agitated, to ensure that particles are randomly distributed in the container, rather than settled at the container bottom after long periods of storage, or deposited upon container walls by centrifugal force from stirring. Before any samples are measured by removal from a container, dissolved gases should be removed by exposing the liquid to low-level ultrasonic vibration and to vacuum just before samples are withdrawn from the container. A sample withdrawal tube should be located with its inlet located in the lower third of the container. Sample volumes sufficient to produce a particle count of 1000 to 10 000 are suggested. The concentration of particles should be at a level where three replicate aliquot samples can be acquired from the container and no more than approximately 75% of the total container volume is removed from the container during this process. Note the particle count for each of the aliquot samples. The count for any sample should not differ by more than 20% from the average for all three samples. The same concern for proper disposal of measured samples and residual liquids in the sample containers and treatment of the containers is required as was used for liquids from process of product line sample disposal.

7.1.4 Inter- and Intrument Variability and Means of Minimizing Differences

As was shown in Figure 2, the scattered light intensity varies markedly with scattering angle for all particles larger than approximately 0.3µm. In addition, Figure 3 points out the differing optical system bases for light scattering particle counters. Considering both situations, it is apparent that the same size and type of particle measured by two dissimilar light scattering OPCs will produce different data. Light extinction OPCs use optical systems with collection angles that may be less than 5°, but scattered light directed out of that small angle will vary with the wavelength of the illumination source for the counter. Extinction counters that are in use now and probably for another decade or so use incandescent filament sources, gas lasers, and solid-state laser illumination sources with significant differences in light wavelengths. For this reason alone, when the calibration particles differ from the particle being measured, instruments with different light sources will generate different data from the measured particles. Although the differences in data are primarily in the reported particle sizes, the effect of reported size differences also affects the reported particle concentration when data on particle size distribution or on particle concentration in a specified size range is required. There are also differences in data from same model OPCs produced by any manufacturer. These arise from the fact that tolerances in manufacturing drawings may be enough to result in scattering angles that can differ slightly between instruments of the same model from any manufacturer. These phenomena may result in production of particle size data differing by no more than a few percent. However, if incorrect calibration materials or procedures are used, or if the instrument calibration is not current, then significant data differences can be expected between instruments. Procedures to minimize interinstrument variability can be summarized as:

1. Use instruments that are similar in design and operation.
2. Make sure that the operators are familiar with instrument operation.
3. Specify a calibration procedure and use calibration particles similar to the particles to be measured.
4. Verify that every phase of the calibration is current.
5. Operate the instrument within its specified capabilities for particle size and concentration.
6. Establish a consistent sample handling protocol

7.2 Calibration Specifications and Procedures

7.2.1 Calibration Specifications

The parameters to be calibrated for any OPC include:

1. Maximum optical and electronic noise pulse generation rate. This rate should be no more than 3–5% of the rate anticipated for the minimum particle counting rate.
2. Fluid sample flow rate. This should be established with minimum accuracy of 95% of the reported inlet sample flow rate.
3. Particle sizing accuracy. This parameter should be established with minimum accuracy of 95% of the smallest reported particle size, based on measuring monodisperse calibration particles with diameters defined by a recognized documented method.
4. Particle sizing resolution. This parameter is the increase in reported relative standard deviation of a monodisperse calibration particle suspension and shall be no more than 5% greater than the stated relative standard deviation of the calibration particles.
5. Particle counting efficiency. This parameter defines the accuracy with which the OPC counts individual particles at the minimum detectable size and at all larger defined sizes. The counting accuracy for monodisperse particles at the minimum detectable size should be 50% ± 10% and the counting accuracy for particles at least 1.5 times larger than the minimum detectable size should be 100% ± 10%.

6. Particle concentration limit. This parameter defines the maximum concentration where the probability of multiple particles within the sensing volume is no more than 10%.

7.2.2 Calibration Procedures

Brief descriptions of calibration procedures for OPCs will be provided here. For further details, the reader is referred to the documents listed in section 6 of this discussion. Section 6.1 lists some calibration procedures for gasborne particle counter performance verification. Section 6.2 lists some operation procedures for gasborne particle counters. Section 6.3 lists some calibration procedures for liquidborne particle counter performance verification. Section 6.4 lists procedures for liquidborne particle counter operation. Complete descriptions of these procedures will not be provided here; the reader is directed to the documented procedures of section 6. Sources for the procedures are also provided in section 6.

7.2.2.1 Performance Calibration Procedures for Optical Particle Counters

Sample Flow Rate. To report suspended particle concentration accurately, the measured fluid sample flow rate into the counter must be defined accurately. Flow is measured by a volumetric flow measurement device that operates with low-pressure drop that will not degrade performance of the counter flow control system. If a mass flowmeter is used for calibration of the sample flow rate for a gasborne particle counter, then correction to the specified ambient or standard temperature and pressure conditions must be calculated and used in the concentration determination. Sample flow rate should be defined with a minimum accuracy of 95%.

Noise Count Rate. Noise count rate calibration is carried out to ensure that data, particularly in the smallest size range capability of the counter, are generated by particles rather than by background noise pulses from the electronics or optical systems. The noise count rate measurement is made by operating the particle counter with particle-free fluid moving through the sensing volume. Recording the noise count rate for a specified time period provides valid data. The noise count rate should not exceed 5% of the count rate anticipated for the anticipated particle count rate.

Particle Sizing Accuracy. Although the particle counter may be used to characterize particles containing materials that vary in shape and composition, a consistent response to selected calibration particles is required. For many OPC sizing accuracy calibrations, isotropic spherical latex particles are most often used for this purpose. A suspension is generated and the modal pulse amplitude of the pulses produced from a batch of particles of known size and relative standard deviation is defined as the signal level for particles of the same size as that batch of calibration particles. Since the OPC response varies significantly with refractive index of the particles being measured, calibration with latex spheres with a refractive index of 1.6 and with no absorption may cause a problem when the counter is to be used for measurement of particles with different optical properties. In this situation, a solution of a known concentration of material with properties similar to those of the material to be measured can be prepared in a liquid with appreciable vapor pressure. Monodisperse droplets can be generated using a vibrating orifice droplet generator; short exposure to air will cause the liquid to evaporate from the droplet leaving a residual particle of the desired physical characteristics. Knowing the size of the monodisperse droplets and the solution concentration, the size of the residual droplet can be calculated and used for calibration purposes. Alternately, polydisperse particles with optical properties similar to the particles to be measured can be used if the particle size distribution for that suspension is known.

Particle Sizing Resolution. This parameter is determined after particle size calibration is carried out for the full size range of the counter being calibrated. If a suitable pulse height analyzer is available, either as an external instrument, or incorporated in the electronic section of the counter being calibrated, data obtained during size calibration can be used to define the relative standard deviation of the pulse height distribution when the monodisperse latex calibration particles are measured. Pulse size data for particles at least twice the size of the lower sizing limit of the counter can be used. These data are converted to values for the average particle size and standard deviation values. The increase (if any) in relative standard deviation, compared to the labeled value of the calibration particles, is reported as the particle size resolution of the counter being calibrated. A maximum reported relative standard deviation no more than 10% greater than that of the calibration particles is acceptable, but resolution values in the 5% range are preferred.
Particle Counting Efficiency. Particle counting efficiency is affected by several factors. If sample flow is not completely contained within the defined sensing volume, some portion of the particles in the sample will not be seen. If sizing resolution is poor, some particles smaller than the lower size boundary of any size range will be reported as being within that range, resulting in excessive particle count data in that range. Counting efficiency for an OPC is determined by producing a well-mixed suspension of particles in a closed chamber. Samples are withdrawn from a single location in the chamber by the counter being calibrated and by a reference particle counting device. That reference device is one that is known to have 100% counting efficiency for the smallest particles in the test suspension. Sample transport to both the counter being calibrated and the reference system uses sample handling systems that are designed so that particle losses during transit from the chamber to both instruments are either negligible or identical. Samples are counted by both instruments and counting efficiency of the calibrated counter is defined as the ratio of the data reported by that counter to the data reported by the reference instrument. Primary counting efficiency data are obtained using suspensions of monodisperse particles. Counting efficiency for specific materials can be procured with a suspension of polydisperse test particles. The counting efficiency so obtained may vary from the primary counting efficiency data.

Particle Concentration Limit. If a high particle concentration may be present in the sampled fluid, more than one particle may be present in the sensing volume at any time. Even if the concentration is known to be no more than the concentration equivalent to one particle per sensing volume, then the fact that particle distribution in the sample is random, rather than uniform, will result in more than one particle being present in the sensing volume at some time. Several small particles may be reported as a single larger particle, resulting in a report of larger and fewer particles than are actually present. As sample concentration increases, the probability of coincidence error also increases. The maximum recommended concentration accepted by many organizations is that where the coincidence error is no more than 10%. The particle concentration limit is determined by producing a series of particle suspensions carefully diluted and sampled by the instrument being calibrated. The initial sample concentration should be in the range between the maximum recommended concentration and twice that level. The diluted suspensions are prepared so that the concentration of each succeeding suspension is reduced by a constant known factor from that of the previous suspension. Dilution ratios between 0.1 and 2 can be selected. The reported concentration of each succeeding suspension is recorded and the reported concentration of that suspension is compared to that of the previous suspension. At concentrations above the maximum recommended concentration capability, the ratio of counts in successive suspensions will be less than the dilution ratio. This indicates that coincident particles were present in the more concentrated suspension. When both suspension concentrations are below the recommended maximum concentration limit, the reported concentration ratio for two succeeding suspensions will be equivalent (95% to 105%) to the dilution ratio. The concentration of the more concentrated suspension at this point is the recommended maximum particle concentration for that particle counter.

7.2.2.2 Operational Procedures for Airborne Particle Counters After the particle counter has been calibrated, it is ready to size and count particles in the sample that is to be measured. However, there are some precautions required to maintain the sample with no artifact introduction or particle loss. The requirement for isokinetic sampling in gases has been discussed previously and will not be repeated here. The procedures for isokinetic sampling involve measurement of the sampled gas stream velocity, knowledge of the particle counter inlet flow rate and selection of an inlet probe dimension that will establish the sample probe inlet velocity at the sampled gas velocity. Even when the particles to be counted are so small so that anisokinetic sampling will not cause particle count errors, isokinetic sampling may still be required to ensure that the sampled gas source can be identified exactly. When air to be sampled is not moving at a constant velocity or is static, isokinetic sampling cannot be used. The primary concern in this situation is collection of particles ≥5 µm with minimum losses. Figure 9 describes the particle size and sampled air-flow parameters that allow accurate sampling for a vertical thin-wall sample probe with an upward-facing inlet. Sampler inlet efficiency is shown as affected by the Stokes number (defined here as the ratio of the stopping distance of a particle to the diameter of the sample probe inlet) and relative settling velocity of the sampled particle (the ratio of the particle settling velocity in still air to the sample probe inlet velocity).

In many air sampling operations for cleanroom performance verification, intermittent sample collection from a number of locations may be required to verify that tool and processing operations are not producing contaminant particles. In this situation, economic and space limitations may dictate a sampling procedure wherein a single OPC is connected to a sampling manifold system. This system consists of sample tubing from each sample point to the manifold system that directs samples to the particle
counter inlet with minimum loss in the transfer process. However, the sample tubes must be configured correctly so there is minimum particle loss in the tubing during transit to the manifold and particle counter. This means that the tubing should not be so long that residence time in the tube will cause excessive loss of particles larger than 1–2 µm due to deposition caused by gravitational or turbulence effects. The tubing should not have an excessively small diameter (<6 mm) or pressure drop in the tubing will reduce the flow excessively. The tubing should have no bends with radius of curvature less than 15 cm to avoid centrifugal effects at the bend. The tubing material should be selected to minimize electrostatic charge by triboelectric effects. Stainless steel tubing is best if permanent installations are considered and cost is acceptable. Reactive metal (copper or aluminum) should not be used. Conductive polymer tubing with conductivity equivalent to that of plasticized polyvinyl chloride is recommended when sample line location or configuration may be modified as product or process changes dictate. Plasticized polyvinyl chloride is quite useful for handling particulate suspensions in many fluids, but even small quantities of the dioctyl phthalate plasticizer vapor may cause problems in product performance. Fluorocarbon or glass tubing is not recommended because of the electrostatic charge generated and retained by this tubing from aerosol flow.

7.2.2.3 Operational Calibration Procedures for Liquidborne Particle Counters The calibration procedures are summarized briefly here. For full details refer to the documents listed in section 6.

Sample Flow Rate and Volume. Liquidborne particle counters measure particles in liquid samples in several possible modes. The sample may be aspirated into the counter sensing volume by placing a batch sample container under the sensing volume, with a tube leading from the container to the sensing volume, reducing the pressure in the sensing volume, and drawing a sample through the sensing volume with subsequent disposal of the tested liquid. The sample may be forced through the sensing volume by increasing the pressure in the sample container to force the liquid upward through the sensing volume. A flowing stream of sample liquid may be forced through the sensing volume by placing a sample line inlet in that flowing stream with the sample line outlet connected to the counter sensing volume.

When aspirating samples from a sample container, the contents of that container must be well mixed before samples are measured. The aspiration process must not reduce the static pressure on the sensing volume to the point where dissolved gas in the liquid will form bubbles or to the point where the pressure in the sensing volume is below the vapor pressure of the liquid at the measurement temperature. When the samples are moved through the sensing volume by pressurizing the sample container, the pressure must be maintained at a constant level or the flow rate will change; this may cause the signal pulses to become so short that erroneous sizes are reported from those pulses. If the flow rate decreases excessively, then the liquid velocity upward through the sample tube to the sensing volume may decrease to the point where the gravitational settling velocity of large particles in that sample may exceed the upward velocity, with the result that no large particles move through the sensing volume. Figure 10 illustrates a pressure feeder for batch liquid samples in a container.

![Figure 10](image-url)
When measuring samples taken from a process or product stream, isokinetic sampling is encouraged, but is seldom required for particles smaller than 10 µm in diameter. Sample removal from a process or product line by a sidestream sample line should be at least 12 line diameters before or after a change in line orientation or size. A sidestream can be removed from the sampled main line and the entire sidestream passed through the sensing volume. The sidestream volumetric flow rate should be controlled so that the flow is equal to the flow at which the particle counter was calibrated. Flow rate through the sidestream line can be measured with an internal flowmeter, preferably a nonintrusive type.

**Background Noise Pulse Rate.** With no liquid flowing through the sensing volume, the electronic system is set to report data in the cumulative mode. The first size range is set to the manufacturer’s level for the lowest size sensitivity of the instrument. Approximately 25 mL of clean liquid is added to a carefully cleaned sample container and the sensor and sample line are flushed with three 10-mL batches of clean liquid without collecting any data. The sample feeder is set to feed a sample of at least 20 mL to the sensing volume for particle measurement. The previous sample passage of three replicate samples is repeated and the particle count data recorded. The average count reported per milliliter of liquid is determined. This value will represent the noise count rate of the instrument. Noise counts should not be generated at a rate greater than 5% of the counting rate anticipated for the samples to be measured.

**Particle Sizing Accuracy.** Two procedures are available for determining particle sizing accuracy. Either monodisperse particles of verified sizes can be used to set the sizing response of the instrument or a suspension of polydisperse particles with a verified size distribution and concentration can be used for that purpose. The choice is based on the degree of similarity of either of these calibration particles to the particulate materials to be measured. When the monodisperse particles are chosen, the procedure for setting the particle counter response is essentially identical to the procedure used for the gasborne particle counter calibration. Use of monodisperse latex particles for sizing calibration is required to calibrate particle counters used for measurement of pharmaceutical and health care products, to verify potable water cleanliness, to measure particles with little absorption, and in areas where measurement of submicrometer particles is required. The polydisperse particles are used to calibrate instruments used for measurement of particle content of hydraulic fluids, fuels, and lubricants. The photomicrographs of Figure 11 illustrate the difference between the two calibration particle types. The monodisperse particles are transparent and identical in size and configuration. The polydisperse particles are irregular in configuration and do not all have the same optical properties, as noted by the differences in shade between different particles.

The cumulative particle concentration per milliliter of suspension can be calculated from data, similar to those shown in Table 1. This table provides an example of the cumulative concentration of polydisperse particles as threshold size increases. Batch-to-batch data will be within the limits given in Table 1 for materials fitting within the specification for ISO ultrafine test dust (UFTD). Similar tabulated information is available for ISO fine, ISO medium, and ISO coarse test dusts to permit calibration over a wider size range.

There is one problem found when using the polydisperse calibration particles that is present with all the ISO test dusts. This problem is caused by the wide range of particle concentrations from the smallest to the largest particles in the batch. The result is that statistically valid particle count data cannot be obtained for the large particle sizes unless the suspension concentration is so high.

that the small particle concentration exceeds the maximum concentration capability of the particle counter. In this situation, calibration for large particle sizing takes advantage of the situation shown in Figure 5. Monodisperse calibration particles can be obtained in the “large” sizes where there are insufficient large particles in the polydisperse calibration suspension for statistically valid data. As seen in Figure 5, the refractive index does not affect the extinction coefficient. Therefore, use of the large monodisperse particles permits definition of the counter response in the sizes where the polydisperse suspension will not provide adequate data.

**Particle Sizing Resolution.** Particle sizing resolution is determined using monodisperse calibration particles at least twice as large as the lower sizing limit of the instrument. The increase in relative standard deviation for the reported particle size range for the monodisperse particles selected for this measurement should be determined. The same procedures used to determine sizing resolution for the airborne particle counter could be used here. Most particle counter specifications for sizing resolution state that the counter will not increase the relative standard deviation shown for the monodisperse calibration particles by more than 10%. If the data fit that level, this requirement is met.

**Particle Counting Accuracy.** A batch of monodisperse particles with diameter in the size range from 5 µm to 25 µm is selected. These limits are chosen to permit ease of viewing at the small size end of the range and to minimize problems of loss due to deposition, settling, or inadequate dispersion at the large particle size end of the range. A suspension of these particles is prepared and the total particle concentration in the suspension is determined. Three aliquot samples of the suspension are passed through the sensing volume of the particle counter being validated and through the sensing volume of a particle counter that has been confirmed to have 100% counting efficiency for the particles in the size range selected. Both counter sensing volumes should be connected in series with a short length of tubing. The counter being calibrated should report count data equivalent to the data reported by the verified counter.

**Particle Concentration Limit.** The maximum concentration that can be accurately measured is limited by the accepted coincidence error. This error is due to the probability that more than one particle is present within the sensing volume at any time. The procedure for determining the maximum concentration limit is to pass a series of diluted suspensions with known dilution ratios through the sensing volume and to note the point at which the reported concentration ratio from one suspension to the previous suspension in the series is equivalent to the dilution ratio for the two suspensions. Since many liquidborne particle counters are used for measurement of a wide range of particle sizes, polydisperse particle suspensions are used to determine the maximum recommended particle concentration for liquidborne OPCs.

8 PERFORMANCE CAPABILITIES OF PRESENT DAY OPTICAL PARTICLE COUNTERS AND POSSIBLE FUTURE DEVELOPMENTS

8.1 Particle Size Capabilities

The smallest discrete particle that can be reliably counted and sized by commercially available OPCs for either gasborne or liquidborne particles is 0.05 µm in diameter. This capability applies for liquidborne particle counters used for measurement of particles in liquids that can be handled in glass and stainless steel with no attack on the counter materials of construction. If liquids as aggressive as hydrofluoric acid are to be used, then the sensitivity is decreased so that the smallest particle reliably counted and sized in those liquids is 0.075 µm in diameter. It is anticipated that the minimum size sensitivity will be 0.03 µm for gasborne particle counters and for liquidborne particle counters handling inert liquids before the end of the year 2000. No estimate of the maximum sensitivity for these instruments can be made at this time, but the need to define particles as small as possible is a continuing demand on the development capabilities of OPC producers. As part of the sizing capability of OPCs, particle sizing resolution is also a performance parameter.
of concern. As an example, the calibration procedures and specifications in the section 6 documents for health care product testing specify that sizing resolution shall be no worse than 10%, particularly for liquidborne particle counters used to characterize large-volume and small-volume injectable liquids. Better control of illumination uniformity from laser light sources is expected to improve sizing resolution for both gasborne and liquidborne particle counters to the point where resolution worse than 5% will not be accepted in the health care product area after the year 2001. The other parameter connected with particle size measurement is the dynamic range of the instrument. This parameter defines the range of particle sizes that can be measured accurately. Particle counters with a 100:1 dynamic range are available. For application to measurement of particles in areas where a wide range of materials are used, a dynamic range of 1000:1 would be required. Use of advanced electronic systems with built-in autoranging amplifier gain control systems will permit operation of the particle counter over larger dynamic ranges. The capability of reporting particle size distribution in a very large number of size ranges has been seen in some listings of particle counter performance specifications. The capability to report accurate size data in more than 16 size ranges requires particle sizing resolution of 5% or better.

8.2 Particle Concentration Capability

In making measurements to characterize the particle content of fluids, the need for statistically valid data imposes a requirement to count sufficient particles to define particle content with a specified confidence limit (often 95%) as rapidly as possible. For gasborne OPCs, the capability of present day counters is adequate for most applications. Counters with gas flow rates of 47 cm³ s⁻¹ or 470 cm³ s⁻¹ can normally handle particle concentrations of 35 cm⁻³ or 3.5 cm⁻³. In situations where the particle concentration to be defined is beyond the capability of the counter, gas dilution can be used to decrease the measured concentration to the capability of the particle counter in use. The dilution system can be selected for a dilution ratio that will permit the true sample concentration to be defined correctly. For consistent measurement mainly of high concentrations of gasborne particles, as may be expected for many atmospheric research studies, optical gasborne particle counters with very small sensing volumes can be used to measure particle concentrations up to 2 × 10⁹ cm⁻³. For valid measurements at such concentrations, sample gas flow rates may be in the range of 0.1 cm³ s⁻¹.

Particle concentrations in liquids are frequently higher than those in gases. Thus, the sample flow rates used in liquidborne OPCs are usually lower than those used for gasborne counters. For measurement of particle concentrations up to 10⁴ mL⁻¹, a liquid sample flow rate of 0.0017 mL min⁻¹ is used. For measurement of particle concentrations up to approximately 35 mL⁻¹, a liquid flow rate of 1.67 mL min⁻¹ is used. Under these conditions, the liquids of concern can be characterized with present day instrument capability. As requirements for product quality increase, it is anticipated that there will be only a minor requirement for instruments that can measure particles in concentrations higher than present day instruments can handle. One example of the area where such a need may exist is in characterization of high-efficiency filter systems where the challenge concentration must be high enough so that even the few particles that penetrate the filter will be sufficient to permit reliable definition of the filter efficiency for particles at the most penetrating particle size.

8.3 Optical Particle Counter Configuration and Size

The particle counter described by Fisher et al. was built in 1954. It operated with an electronic system using vacuum tubes. The optical system used an incandescent filament lamp for illumination and a photomultiplier tube photodetector. The electronic system required two 1.8-m relay racks to contain those components. The optical system was a right angle scattering system using lenses to direct the illumination beam and to collect the scattered light. The optical system weight was approximately 67 kg and the electronic system weight was approximately 135 kg. The instrument counted and sized particles from 1 to 64 μm in 12 size ranges. The sample air flow rate was 47 mL s⁻¹ and the maximum concentration capability was 1.1 particle cm⁻³. This instrument can be compared with a recently described high-sensitivity airborne particle counter. The counter is capable of counting and sizing airborne particles ≥ 0.05 μm in an air sample flow of 47 mL s⁻¹. The illumination source is a solid-state laser. Parallel processor array detection permits background noise from air molecule scattering to be minimized. Light scattering over a scattering angle of 90° ± 45° is collected by Mangin mirrors (concave spherical mirrors that collect and focus light to the photodetector) and focused upon a solid-state photodetector array. This instrument has a dynamic range capability of 100:1, allowing measurement of particles from 0.05 to 5 μm in diameter with sizing resolution of 3%. Data are reported in eight size ranges in either tabular or graphical format. The maximum recommended particle concentration is 35 cm⁻³. Instrument operating parameters and data processing are controlled by an internal microprocessor. The entire instrument is in a package with dimensions of 100 cm width, 175 cm depth, and 25 cm height. The weight is approximately 15 kg. Data from this instrument can be
The comparison between the counter described in 1955 and that described in 1988 indicates that developments in performance have continued and that improvements in the performance of these instruments have not stopped. It is anticipated that future development will result in sensitivity to smaller particles—at a relatively slow development rate—and better sizing resolution as illumination source uniformity improves. The detection capability will also be modified. By adding a photodetector capability at wavelengths other than that of the illumination source, identification of some particle chemical composition becomes possible. This feature is being developed to identify microbiological materials and will probably be extended to other materials as new lasers are developed with more emission wavelengths. This type of activity is mainly aimed at identification of material type (organic, inorganic, etc.). Laboratory instrumentation for detailed analysis of single micrometer size particles has been used for several years. Aerosol particles were collected and were analyzed by electron probe X-ray microanalysis and laser microprobe mass analysis. These techniques were used for trace element measurements by particle-induced X-ray emission. As more powerful lasers become available, the possibility of real-time analysis of individual airborne particles drawn into an instrument and analyzed in situ becomes a distinct possibility. This will permit identification of sources when ambient air pollutants are measured, as well as controlling product uniformity for powders.

Other areas where changes can be expected are in the counter size, functions, cost, and maintenance requirements. Better portability of OPCs has been a need expressed by users where modifications in process or product require measurements at different locations on an unscheduled basis as required by changing process conditions. This is a particular need when personnel must have a particle counter at a location where access is difficult or adequate space is a problem. The need for portable OPCs has resulted in development of battery-operated counters that are handheld, weigh 1 kg or so, and are capable of counting and sizing particles > 0.3 μm in sample air flows of 47 cm³ s⁻¹. These counters can report data in two to six particle size ranges. The electronic system can include a data storage capability of several hundred measurements with records of sample point location, time of measurement, and particle concentration data in the specified size ranges. Internal components are easily and quickly removable and replaceable with calibrated components that are kept in stock and can be inserted by any technician with minimum training required. A routine calibration procedure can be carried out in a central metrology facility for these components.
shipments to and from a central repair and calibration facility may become the maintenance procedure for these and many other instruments. If this situation occurs, then capital costs for the OPC will drop to some extent and the labor costs for service will decrease even more.

Photon Correlation Spectroscopy in Particle Sizing

Walther Tscharnuter
Brookhaven Instruments Corporation, Holtsville, NY, USA

Photon correlation spectroscopy (PCS) has become a powerful light-scattering technique for studying the properties of suspensions and solutions of colloids, macromolecules and polymers, that is absolute, non-invasive and non-destructive. This text explains the principles of the technique and describes the required instrumentation. It also discusses new developments in instrumentation, which may substantially impact on future applications of this technique. Proper sample preparation is of major importance for the accuracy and precision of the mean size and size distribution results and thus one section is dedicated to sample handling.

1 INTRODUCTION

The acronym PCS is only one of several different names that have been used historically for this technique. The first name given to the technique was quasi-elastic light scattering (QELS) because, when photons are scattered by mobile particles, the process is quasi-elastic. QELS measurements yield information on the dynamics of the scatterer, which gave rise to the acronym DLS (dynamic light scattering). Another name, IFS (intensity fluctuation spectroscopy) was used by several authors in the past. Throughout this text the acronym DLS will be employed because its use has become more prevalent and presents a logical juxtaposition to SLS (static light scattering). Application of the DLS technique to particle sizing and commercial availability occurred only about seven years after the first size measurements were made in 1972 merely to check the alignment of a multi-angle research light scattering system. Slowly, through the 1970s, DLS gained wide acceptance among experts in light scattering. This text is not meant to be exhaustive and emphasizes the application of DLS for particle sizing which relates to the translational motion (diffusion) of particles in liquids. However, DLS, by its nature, is not limited to this mode: any time variable parameter, such as the rotation or vibration of scattering centers, or fluctuations in the refractive index, entropy, thermal diffusivity etc. can be measured. The reader is referred to the extensive literature that exists on these subjects.

2 HISTORY

All materials scatter and absorb light and since the first light-scattering experiments described by Tyndall, SLS experienced major developments in the first half of the 19th century and is well described in the publications by Kerker. DLS theory is built upon the earlier foundation of classical light-scattering theory, which is usually dated from the 19th century.
by Rayleigh’s papers\(^4\) in 1871 on the scattering from a single particle small compared to the wavelength of light. Scattering from larger particles was added later and is known as Mie scattering, which gives the complete solution for spherical particles of any size. As early as 1908 the temporal fluctuations about the average scattered light intensity were identified with the motion of the particles and their diffusion coefficients. Einstein\(^5\) had already published the relationship between diffusion and size, so in principle the way was open for the birth of a new particle sizing technique. The fundamentals have been written about very often and these references should be consulted for a more complete treatment.\(^6–26\)

The history of experimental DLS begins with the advent of the laser. In the early 1960s Pecora\(^27\) pioneered a new kind of light scattering: *time dependent* light scattering. He showed that, by analyzing the frequency distribution of the intensity fluctuations of light scattered from suspensions of macromolecules, information can be obtained about the translational and rotational diffusion coefficients of the macromolecules. Initially DLS was used to measure the diffusion coefficient of macromolecules, from which a hydrodynamic size was calculated. A few industrial users tried this technique for submicron particle sizing, mostly to replace transmission electron microscope (TEM) measurements in quality control (QC) applications. During the second half of the 1970s microscope (TEM) measurements in quality control particle sizing, mostly to replace transmission electron

### 3 PRINCIPLES OF DYNAMIC LIGHT SCATTERING

#### 3.1 Origin of Intensity Fluctuations

Colloidal sized particles in a liquid undergo random ("Brownian") motion owing to multiple collisions with the thermally driven molecules of the liquid. The scattered light intensity from these diffusing particles will fluctuate in time, thus carrying information about the diffusion coefficient of the particles. Cummins, Knable and Yeh\(^30\) demonstrated a method to determine the spectrum of light scattered from a dilute suspension of polystyrene spheres by employing novel optical techniques. Following is a description of the basic physics of the DLS technique and of the instrumentation employed in these measurements. The approach used is not intended to be exhaustive; for more details, the literature presented at the end of this article should be consulted. The NATO proceedings edited by Cummins and Pike\(^27,3\) are particularly valuable.

The volume edited by Chu\(^29\) conveniently collects many of the major papers together. The article by Ford\(^25\) provides an excellent introduction to many of the practical aspects of the technique and the book by Wyn Brown\(^29\) contains many valuable contributions to various data transformation methods. Equation (1) describes the time-averaged scattered intensity \(\langle I(q) \rangle\) in terms of particle parameters (also see Figure 1)

\[
\langle I(q) \rangle = KNM^2 P(\Theta)B(c)
\]

(1)

\[
q = \frac{4\pi n}{\lambda_0} \sin \left( \frac{\Theta}{2} \right)
\]

(2)

where \(q\) is the magnitude of the scattering vector, \(\Theta\) is the scattering angle, \(\lambda_0\) is the wavelength of the laser in vacuo and \(n\) is the refractive index of the suspending liquid; \(K\) is an optical constant, \(N\) is the number of scattering particles, \(M\) is the mass of a particle, \(P(\Theta)\) is the particle form factor, and \(B(c)\) is the concentration factor. The terms \(M^2\) and \(P(\Theta)\) are of particular importance for the determination of size distributions. The central concept in DLS is as follows: the diffusion of the scatterers (Brownian motion) causes the phases of the fields scattered from each of them to change with time so that the *total* scattered intensity will fluctuate with time owing to constructive and destructive interference. The source of the intensity fluctuations can be understood with reference to Figure 1. A laser beam of wavelength \(\lambda\) is incident on two identical particles. Light scattered by the particles is received by a photo multiplier tube (PMT) and it can be readily seen that the pathlength...
difference between the scattered waves is \(d_p \sin(\theta)\). When this pathlength difference is equal to an integer multiple of wavelengths \(d_p \sin(\theta) = m\lambda\), the wavelets will arrive at the detector in phase (constructive interference), i.e. the total intensity will be twice that from a single particle. When the pathlength difference is a half integer multiple of wavelengths \(d_p \sin(\theta) = \lambda/2, 3\lambda/2, 5\lambda/2, \ldots\), then the two wavelets will be exactly out of phase (destructive interference), i.e. the resulting intensity will be zero. The relative positions and orientations of the particles undergo Gaussian random changes in time (Brownian motion). The result is a total intensity which fluctuates in time from zero to double the single particle scattered intensity. In a real experiment there are perhaps \(\sim 10^8\) particles in the scattering volume, and the total intensity is the result from the interference between the scattered fields from all of these. As a consequence, the intensity \(I(t, q)\), as seen by the detector, will be a randomly fluctuating signal as shown. Its well-defined mean value, \((I(q))\), is the quantity measured in a SLS experiment. The intensity fluctuations are not readily observed because they occur on a rapid timescale \((10^{-6}-10^{-3} \text{ s})\) and because they take place only at a point (Ford\(^{31}\)). The first condition necessitates a high-speed detection and recording system. The second condition is of fundamental importance in DLS measurements because it determines the limiting properties of the optical system. When the light scattered from a suspension of colloidal particles undergoing Brownian motion is projected onto a screen or wall, a granular pattern ("speckles", bright and dark patches) is observed. The integral intensity appears constant. However, the intensity of each individual speckle changes randomly in time from very dark to very bright. The intensity of adjacent spots also fluctuates, but independently. Thus the largest spread in intensity (the fluctuations) will be obtained by looking at exactly only one spot. As the number of spots observed increases, the magnitude of the fractional intensity fluctuations will decrease, because the spots’ intensities fluctuate independently and the high probability of one spot’s intensity increasing and another’s decreasing yield small integral fluctuations, even though the total time averaged intensity increases by observing several speckles simultaneously. The intensity fluctuations will be in phase, or coherent, if the light is detected over one “coherence area” (one speckle) the size of the coherence area. For the configuration shown in Figure 1, where a scattering volume of diameter \(d_p\) is a distance \(R\) away from a detector, the size of the coherence area \(A_{coh}\)\(^{(15)}\) is given by Equation (3):

\[
A_{coh} = \frac{4\lambda^2 R^2}{\pi d_p^2}
\]

(3)

The area of the detector is given by Equation (4)

\[
A_{det} = \frac{\pi d_{det}^2}{4}
\]

(4)

and if this is set equal to \(A_{coh}\), the size of the detector that is sufficient to see only one coherence area may be calculated. For a typical arrangement with \(\lambda = 475\ \text{nm}\) (HeNe laser wavelength in water), \(R = 15\ \text{cm}\) and \(d_p\) (the diameter of the scattering region) = 0.2 mm, the diameter of the detector \(d_{det}\) will be \(\sim 0.9\ mm\) for one coherence area, i.e. a detector aperture of \(\sim 0.9\ mm\) is required to see one spot and achieve the maximum signal-to-noise ratio (S/N). Since there is no advantage for most experimental conditions in collecting more than one coherence area, it is important to have the maximum intensity scattered into a small area. This is achieved by tightly focusing the incident beam to decrease \(d_p\) and increase the size of the coherence area (Equation 3).

### 3.2 Detection Limits and Ranges

Several experimental conditions must be met for the applicability of the relevant physics for SLS and DLS techniques in general, and particle sizing in particular (also see Table 1 in section 4):

#### 3.2.1 The Optical Mixing Mode

Any measurement must use exclusively one of the following three optical mixing modes:

<table>
<thead>
<tr>
<th>Condition</th>
<th>Cause</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>Multiple scattering present</td>
<td>Concentration too high</td>
<td>Measured sizes too low</td>
</tr>

<tr>
<td>Sample preparation</td>
<td>Impatience or ignorance</td>
<td>Incorrect or unrepeatable results</td>
</tr>
</tbody>
</table>
• Self beating: the scattered light mixes on the photo multiplier cathode with itself.
• Homodyning: the scattered light mixes with a strong signal from the same laser. This signal, a local oscillator, must have the same frequency, must be at least an order of magnitude higher than the scattered light, and must be in phase with it. If the auto correlation function (ACF) contains a mix of self beating and homodyning, the calculated sizes are invalid. Unfortunately there is no easy way to recognize this problem when it is present. Only one commercially available instrument employs the homodyning mode for particle sizing.\(^{[22]}\)
• Heterodyning: the scattered light mixes with a strong signal of a different frequency (a local oscillator), which is generated either by frequency shifting the same laser or by using a laser beam with a different frequency.

It should be noted that in the literature the terms self-beating and homodyning are frequently used interchangeably and homodyning is confused with heterodyning. Here these terms are used according to their true definitions: DLS-based particle sizing applications operate almost exclusively in the self-beating mode, homodyning is used rarely and heterodyning is not employed at all. However, DLS Doppler (velocimetry) experiments are conducted almost exclusively in the heterodyne mode.

### 3.2.2 Concentration

The concentration must be sufficiently low so that in Equation (1) \( B(c) = 1 \) and multiple scattering (see below) is avoided, but also must be sufficiently high to prevent signal distortions due to number fluctuations. The number of the particles in the scattering region must always be sufficiently high to maintain a constant \( I(q) \) (Equation 1).

### 3.2.3 Multiple Scattering

Unless the concentration is vanishingly small, any scattered photon has a non-zero probability to be scattered again while traveling through the sample. The ACF of such multiple scattered light decays faster, yielding an apparent smaller particle size. Thus the sample concentration must be kept sufficiently low and/or the optical path must be sufficiently short to avoid multiple scattering.

### 3.2.4 Ergodicity

All particles must have an equal opportunity to be measured. This condition is sometimes difficult to meet if the diffusion coefficient of the scatterers is very low, see Pusey.\(^{[19,33]}\)

### 3.2.5 Stationary Process

Scattering conditions must not change during the measurement.

### 3.2.6 Stray Light

Stray light must be avoided to prevent inadvertent homodyning (see section 3.2.1) and commonly determines the low limit of the angular measuring range.

### 3.2.7 Sample Preparation

The term \( M^2 \) in Equation (1) predicts the scattered intensity to be \( \propto d^6 \). Consequently a few large particles (commonly called “dust”), will overwhelm the desired signal (see section 4).

### 3.2.8 Size Range

The DLS technique is commonly employed in the range of 0.002 to 2 microns. The low limit is usually determined by the available laser power. The high limit results from sedimentation and number fluctuations due to the low number of large particles that fit into the small scattering volume.

### 3.2.9 Measurement Duration

The typical range is from 1 to 10 minutes, depending on \( \langle I(q) \rangle \).

### 3.3 Time Domain Data Acquisition of a Random Signal (Correlation)

To see how the signal \( \langle I(q) \rangle \) changes with time it is convenient to compute its ACF. The intensity ACF is described by Equation (5):

\[
\overline{G^{(2)}(t_d)} = \frac{1}{N} \sum_{i=1}^{N} I(t_i)I(t_i - t_d) = \langle I(t)I(t - t_d) \rangle \quad (5)
\]

The angle brackets indicate a time average, \( N \) is the number of samples and \( t_d \) is the time delay between the samples. Experimentally, \( G^{(2)}(t_d) \) is determined by recording \( I(t) \) at time intervals much shorter than the timescale of typical fluctuations and accumulating the products of the intensities as a function of \( t_d \). For a dilute suspension of monodisperse spheres (e.g. latex particles), \( G^{(2)}(t_d) \) can be written as Equation (6):

\[
G^{(2)}(t_d) = B + f \times e^{-2\nu t_d} \quad (6)
\]
where $B = \langle I \rangle^2$ (Figure 1) is the baseline, $f$ is an instrumental constant and $2\Gamma$ is the reciprocal of the decay time $\tau$. $G^{(2)}(t_d)$ is normalized by dividing Equation (6) into the base $B$, yielding in Equation (7) the normalized intensity ACF $g^{(2)}(t_d)$. For Gaussian statistics Glauber(34) derived Equation (7) via the Siegert relation(35)

$$g^{(2)}(t_d) = 1 + a[g^{(1)}(t_d)]^2$$  \hspace{1cm} (7)

relating the electric field ACF $g^{(1)}(t_d)$ to the measured intensity ACF $g^{(2)}(t_d)$, and $a$ is an instrumental constant that is now between 0 and 1. It should be noted that any photoelectric detector is sensitive to the intensity of light, which is the square of the field amplitude. The normalized electric field ACF $g^{(1)}(t_d)$ may be written as Equations (8) and (9):

$$g^{(1)}(t_d) = G_0 e^{-t_d/\tau}$$  \hspace{1cm} (8)

$$\Gamma = \frac{1}{\tau} = D \tau q^2$$  \hspace{1cm} (9)

where $\tau = 1/\Gamma$ is the decay constant and $D_\tau$ is the translational diffusion coefficient of the spheres, and $G_0$ is the intercept of the exponential function, $g^{(1)}(t_d = 0) = 0$. In the case of measurements on dilute monodisperse spheres, the intensity ACF will be a simple exponential function as shown in Figure 2. The significant parameter in Equation (8) is $\tau$, which is invariant to the scattered intensity $\langle I(q) \rangle$. Thus, for DLS-based measurements, the absolute intensity is of secondary importance, as long as it is sufficiently large to complete the experiment within the lifetime of the operator or the stability of the sample, whichever comes first. Measurements in the frequency domain yield the same information; in Equation (10) the power spectral density $S(w)$ is the Fourier transform of $g^{(1)}(t_d)$ and has the shape of a Lorentzian.

$$S(w) = \langle I(\tau) \rangle \frac{(2\Gamma)^2}{w^2 + (2\Gamma)^2}$$  \hspace{1cm} (10)

The relationship between $\Gamma$ and $\tau$ is defined in Equation (9), from which the particle diffusion coefficient $D_\tau$ can be calculated. Finally in Equation (11), for spheres, $D_\tau$ is related directly to their hydrodynamic radius $r_h$ by the Stokes–Einstein relationship

$$D_\tau = \frac{k_B T}{6\pi \eta(T) r_h} = \frac{k_B T}{5\pi \eta(T) d_h}$$  \hspace{1cm} (11)

Here $k_B$ is the Boltzmann constant, $T$ is the absolute temperature (Kelvin) and $\eta(T)$ is the viscosity of the suspending liquid (the viscosity is strongly temperature-dependent, requiring a constant temperature throughout a measurement); $r_h$ and $d_h$ are the hydrodynamic radius and diameter respectively; these values are almost always larger than the dry particle diameter owing to the “double layer” that forms around charged particle surfaces. The counter-ions around the particle form a diffuse region which moves with the particle. An important parameter for colloidal stability, the “zeta potential”, is defined at approximately the location of the shear plane (the outer “edge” of the diffuse double layer).

3.4 Data Reduction and Transformation

The simplest case involves a single exponential decay for a monodisperse sample as shown in Figure 2 (owing to the logarithmic time axis, the ACF is ‘S’ shaped). After dividing the correlation coefficients into the baseline and subtracting 1, the remaining part, $G_0 e^{-\tau}$, is fit using a least-squares technique. The value of $G_0$ typically varies from 0.1 to 0.9 depending on the optical configuration. $G_0$ is a maximum when the coherence criterion is met. The particle diameter is calculated from $D_\tau$ in Equation (11). Typical results on latex spheres show the technique is as reliable as an electron microscope on monodisperse samples or latex spheres. The size calculated from Equation (11) is a hydrodynamic diameter.

3.4.1 Monodisperse Distribution

The results for monodisperse samples can be compared directly with other techniques since there is only one “average” diameter. For nonspherical particles either the results can be interpreted in terms of an equivalent sphere diameter equal to the Stokes–Einstein hydrodynamic diameter, or the diffusion coefficient can be interpreted in terms of ellipsoids of revolution.(36) This requires either independent knowledge of one dimension or their ratio.

![Figure 2 Semi-log plot of a single mode ACF.](image-url)
3.4.2 Polydisperse Distribution

The interpretation of data from polydisperse samples (Figure 3) is considerably more difficult. Since the technique does not count single particles, size distribution information must be obtained from the deconvolution of the sum over all the single exponentials contributing to the measured ACF. The general deconvolution of a sum of single exponentials is difficult. The problem may be summarized by Equations (12) and (13) which define the normalized field ACF $g^{(1)}(t_d)$ as the sum of $m$ particle sizes, each of which contributes $G(\Gamma)$ for the $i$-th size class.

$$g^{(1)}(t_d) = G(\Gamma_1) e^{-\Gamma_1 t_d} + G(\Gamma_2) e^{-\Gamma_2 t_d} + \ldots \tag{12}$$

$$= \sum_{i=1}^{m} G(\Gamma_i) e^{-\Gamma_i t_d}$$

Here $\Gamma_i$ is the value as defined in Equation (9). For the limit of $\Gamma_{i+1} - \Gamma_i = \Delta \Gamma = 0$, $g^{(1)}(t_d)$ is defined in Equation (13) by integrating over the entire range of particle sizes

$$g^{(1)}(t_d) = \int_{\Gamma_{\min}}^{\Gamma_{\max}} G(\Gamma) e^{-\Gamma t_d} d\Gamma = \frac{\Gamma_{\max}}{\Gamma_{\min}} G(\Gamma) e^{-\Gamma t_d} \tag{13}$$

where $G(\Gamma)$ represents the distribution of line widths due to the distribution of particle sizes. $\Gamma_{\min}$ and $\Gamma_{\max}$ define the range of line width; in principle, $\Gamma_{\min} = 0$ and $\Gamma_{\max} = \infty$. It is easy to calculate $g^{(1)}(t_d)$ from a known size distribution $G(\Gamma)$, but exceedingly difficult to perform the inverse transformation to extract $G(\Gamma)$ from $g^{(1)}(t_d)$. Equation (13) belongs to a class of linear transformations (Laplace) that are known to be ill-conditioned. In the presence of any noise, many different solutions for the functional form of $G(\Gamma)$ are possible. A repeat measurement on the same sample will yield a slightly different $g^{(1)}(t_d)$ with a slightly different noise contribution, resulting in a different $G(\Gamma)$ and hence in a different size distribution $G(d)$. This behavior can render the results of a DLS instrument apparently “not repeatable”. For these fundamental reasons of physics DLS will not become a high-resolution technique for particle sizing. Numerical solutions of Equation (13) were attempted by Chu and Gulari, McWhirter and Pike, McWhirter and Ostrowsky and Pike.[38] have demonstrated that $G(\Gamma)$ can be calculated at exponentially spaced delay times. The method, called exponential sampling introduces $\sigma_0$ as a parameter that limits the resolution of $G(\Gamma)$ for a given noise level in Equation (14).

$$\Gamma_{i+1} = \Gamma_i e^{\frac{t}{\sigma_0^2}} \tag{14}$$

Here $\sigma_0$ is the largest value for a fixed noise content of $g^{(1)}$ and therefore defines the best possible resolution for $\Gamma_i$ and $\Gamma_{i+1}$. Example: if $\sigma_0 = 3.14$, $\Gamma_{i+1}/\Gamma_i = 2.71$; if $\Gamma_{i+1}$ corresponds to a size of, e.g. 500 nm, the next neighboring peak cannot be closer than 184 nm (500/2.71) or 1050 nm (500^*2.71). If the inversion routine asks for a higher resolution than can be supported by the ACF, the Gamma distributions will exhibit more and more artifacts such as additional maxima and negative values for $G(\Gamma)$. The practical limit for the ratio $\Gamma_{i+1}/\Gamma_i$ is 2.

It is important to note, that this resolution cannot be exceeded by any transformation routine without imposing additional, a priori imposed, constraints. The most commonly applied constraints are non-negativity (only zero or positive $G(\Gamma)$ are allowed), range limitations and force fits to specific distribution models (log-normal, bimodal). Provencher, CONTIN contains a non-negative least square inversion software package, CONTIN, which is a generalized Inverse Laplace Transform with constraints and parsimony. CONTIN contains a non-negative least square routine (NNLS), that may be used effectively as a fast executing stand-alone program to obtain rapid size distributions in real time during data acquisition. Several other inversion programs are in use by practitioners, e.g. “Maximum entropy”, “REPEES”[46] and “Single value decomposition”. H. Ruf[49] investigated the errors that are introduced into the inversion process owing to normalization errors. Aside from the noise content of the ACF, baseline errors contribute a significant amount of ambiguities to any of the transformation routines and repeated, iterative, normalizations of the ACF can improve the stability of the results. The above approaches show that only a few parameters of the distribution can be calculated from typical experimental measurements of the correlation function. Present work on these advanced techniques is focusing on the separation of only two peaks.

Figure 3 Bimodal distribution of an emulsion.
in a size distribution, the size ratio of which is at least 2:1. Thus DLS measurements must be considered as relatively insensitive to the particular size distribution and only a few moments of the distribution can be obtained, except for monodisperse samples, for which the technique works extremely well.

### 3.4.3 Cumulants

The most widely used and simplest data analysis technique to apply is the method of cumulants. The method proceeds by expanding Equation (13) about an average line width \((\Gamma)\), to give Equation (15):

\[
\ln[a_0 g^{(1)}(t_d)] = a_0 - (\Gamma)t_d + \frac{\mu_2}{2}t_d^2 - \frac{\mu_3}{6}t_d^3 + \cdots
\]

where \(a_0\) is a constant and \((\Gamma)\), \(\mu_2\), etc. are moments of the line width distribution \(G(\Gamma)\). In practice only the first two moments are obtained with certainty, and care must be taken to limit the range of \(t_d\) such that higher order terms are negligible. Before the advent of non-linearly spaced correlator channels this used to be difficult for broad distributions. This technique has the advantage that no assumption about the form of the distribution is necessary, and, under the correct experimental conditions described earlier, the moments are well defined and useful parameters. It has been shown by Brown, Pusey and Dietz that (Equation 16):

\[
(\Gamma) = \langle D_T \rangle q^2
\]

where \(\langle D_T \rangle\) is given by Equation (17),

\[
\langle D_T \rangle = \frac{\sum N_i M_i^2 P_i(\theta) D_i}{\sum N_i M_i^2 P_i(\theta)}
\]

\(NM^2P\) is the time-averaged intensity weighting factor (Equation 1) for the contribution of \(D\) in the \(i\)-th size class. The sum is over all the particles contributing to the scattering, and it has been assumed that the measurements have been made or will be extrapolated zero concentration. If not, the interparticle interference term \(B(c)\) must be included in Equation (17). It has also been assumed that the optical constant \(K\) in Equation (1) is the same for all particles independent of size. \(K\) includes the refractive index increment (change of solution refractive index with particle concentration). So the assumption of a constant \(K\) means assuming a sample of homogeneous composition independent of size. For Rayleigh scatterers (\(d \ll \lambda\)) and for all particles where measurements have been extrapolated to zero angle, where \(P(\theta) = 1\), and

\[
\langle D \rangle = \langle D \rangle_z = \frac{\sum N_i M_i^2 D_i}{\sum N_i M_i^2}
\]

Here \(\langle D \rangle_z\) is the well-defined \(z\)-average diffusion coefficient (\(z\)-weighting means the next higher weighting after volume). Thus, for spheres, where \(M^2 \propto d^6\), the average particle size obtained is (Equation 19),

\[
\frac{1}{d_z} = \frac{\sum N_i d_i^z}{\sum N_i d_i^z}
\]

Here \(d_z\) is the inverse, \(z\)-average diameter and \(N_i\) is the number of particles in the \(i\)-th size class. The second moment in the cumulant analysis, \(\mu_2\) in Equation (20) yields (after extrapolation to zero concentration and zero angle)

\[
\mu_2 = \langle D_z^2 \rangle - \langle D_z \rangle^2
\]

which is the variance of the \(z\)-average diffusion coefficient distribution. For spherical particles the first term can be related to the inverse square, \(z\)-average diameter, \(\langle 1/d_z^2 \rangle\). This technique has the advantage that no assumption about the form of the distribution is necessary, and the moments are well defined and useful parameters. A convenient polydispersity index is defined as \(Q\) in Equation (21)

\[
Q = \frac{\mu_2}{(\langle D \rangle)^2}
\]

where \(\mu_2\), \((\Gamma)\) and \(\langle D \rangle\) are defined in Equations (20), (16) and (17) respectively. For QC measurements the exact interpretation of data is not usually of primary importance. In this case, measurement at one angle, usually \(90^\circ\), is sufficient to establish an apparent average size and apparent measure of the width of the size distribution. Monitoring changes in these two parameters may be all that is required. In many cases the distribution is known to be log-normal or reasonably close to one; Thomas showed that in this case the two parameters \(\mu_2\) and \((\Gamma)\) may be mathematically transformed to geometric standard deviation and mass mean diameter, the two parameters that define a log-normal function. Such transformations are not limited to log-normal functions but can be performed for any other two parameter distribution. It is important, however, not to forget that this function may or may not resemble the real particle size distribution, although it definitely will produce a “nice” looking display on the computer screen.

### 4 SAMPLE PREPARATION

#### 4.1 Concentration

Concentration effects manifest themselves in two fundamentally different ways:
4.1 Multiple Scattering

Even if $D_T$ is indeed independent of $c$, the “particle size” will be reported as too small, because the correlation is lost on a shorter timescale for multiple scattered photons. A comparatively new set of experiments has been successful in analyzing the dynamics of multiple scattered photons from concentrated samples (see section 9).

4.1.1 Multiple Scattering

4.1.2 Particle–Particle Interaction

The apparent viscosity depends on particle–particle interaction. In sufficiently high concentrations where particles experience significant interactions, the calculated particle size is different from those obtained under infinite dilution conditions. There is a large amount of physics to be learned from such experiments, as long as the instrument is capable of eliminating multiple scattering effects, so that the true functional form of $D_T(c)$ can be obtained and the theories for particle–particle interaction can be investigated (see section 9).

4.2 Stability of Samples

The scattering environment must not change during the measurement. Sometimes this is difficult or impossible to accomplish owing to the presence of changing chemical and/or physical parameters in the sample (chemical reactions, aggregation, temperature). If those changes are the objects of investigation, the experiment duration must be kept sufficiently small compared to the characteristic times of the reactions. Under most operating conditions, however, an unstable sample is the result of inappropriate sample preparation. The following describes a general approach to solving the sample preparation problem as it relates to particle sizing.

4.2.1 Coagulation

Physics predicts (van de Waals forces) that, allowing for a sufficiently long time, any colloidal dispersion will coagulate, be it seconds, minutes or years. Thus the problem to be solved can be stated very simply: how long is stability required? For particle sizing typically 30 minutes are sufficient, but for a commercial product a long shelf life is imperative. It will exceed the scope of this text to dwell on any details, but fortunately even only superficial attention to some basic surface chemistry will result in meaningful particle size measurements. Under most operating conditions an unstable sample is the product of inappropriate sample preparation. The following describes a general approach to sample preparation as it relates to particle sizing.

4.2.2 Hydrophobic or Hydrophilic Sample Surfaces?

Sprinkling a few particles on the surface of the water will rapidly reveal their properties: hydrophilic particles will rapidly disperse in the water, hydrophobic types will stay on the surface. The former will generally merely require a stabilizing surfactant, whereas the latter often can be converted into a hydrophilic system by creating a paste of the particles and methyl alcohol.

4.2.3 Zeta Potential

The “zeta potential” of particles (a measurement of the electrostatic repulsion between particles) is a good, but certainly not the only, predictor of the stability of a suspension. Unless the sample is sterically stabilized, a low zeta potential increases the probability for aggregation within a short time; thus the determination of this parameter is very important. Frequently a simple change of the pH value is all that is required to achieve a stable suspension. Further information about electrophoretic mobility (zeta potential) and the stability of colloidal systems can be found in a book by Hunter.

4.3 Dust in the Sample

The appropriate use of surfactants to avoid aggregation, filtering, centrifugation, ultrasonication, cleaning of sample cells and the use of deionized and filtered water are of utmost importance for any serious size measurement. Dust will not only cause huge intensity spikes and distort the raw data but can also introduce unintentional homodyning to the self-beating mode by actually creating a local oscillator. Nonaqueous (nonpolar) liquids do not attract “dust” as much and are easier to clean, but sample preparation is often more complicated. Filtering of all liquids, especially water, and thorough cleaning of all sample cells as well as pipets, syringes, etc. are always required. DLS instruments, by their nature, will collect at least the dark counts from a detector, always resulting in some nonzero ACF. The computer will happily calculate a “result”, regardless of the quality of the signal, thereby creating insidious and serious problems if any of the above listed conditions is violated. Table 1 shows a compilation of the most common error sources in DLS particle size measurements.

5 INSTRUMENT PERFORMANCE

5.1 Efficiency of Data Acquisition

The ACF consists of many product terms which asymptotically converge to a steady function. The overall
optimization of the statistics begins with the efficient launching of the laser beam, the collection of the scattered photons by bulk or fiber optics and the quantum efficiency (QE) of the detector. All available photon pulses should be utilized by the optics and the electronics in order to achieve the best possible statistics in the least amount of time. Here the design of correlators that do not require any prescaling presents a significant advance in this technology. Modern correlators do not depend on raw computer speed for data collection, but in QC applications the “throughput”, which includes data reduction, display, storage and possible statistical process control (SPC) depends on the performance of the attached data processor.

5.2 Result Verification

DLS results are sometimes not easy to interpret since there always will be some result displayed. Several conditions can be stipulated for the correctness of the results:

- **repeatability**: this is a necessary, but not a sufficient condition;
- **invariance of the size distribution** to the delay time range, as long as the smallest range covers the set of decay times;
- **invariance of the peak positions** to the chosen range of particle sizes;
- **no peaks at the extremes** of the chosen size range;
- **consistency of the results** with the physical and chemical properties of the particles;
- **consistency** of the results with other sizing techniques.

If data transformations are required they must be evaluated very carefully (see section 3).

5.3 Standardization

The International Organization for Standardization (ISO) published a draft paper that proposes to establish “standard” methods for the application of the DLS technique to the measurement of particle size distribution of samples with specified properties. Details of the proposal can be found in the publications of the subcommittee.\(^{54}\) It should be noted that this publication is just a proposal subject to amendments. It presents a framework of design rules for DLS-based particle sizing that should yield results which are invariant to specific instruments or operators around the world.

6 INSTRUMENT DESIGN FOR DYNAMIC LIGHT SCATTERING

A typical DLS system may be broken down into several functional components which will be discussed separately. These are a light source, an optical system, a detector system and a digital correlator.

6.1 Light Source

Practical requirements for a sufficiently intense light source demand a narrow-band, polarized, monochromatic, CW laser. Table 2 summarizes the popular options available.

DPSS have become widely available within the last few years. Their wavelength is typically 532 nm (frequency doubled from powerful 1064 nm diode lasers) and their other properties match well with the requirements of DLS instruments.

6.2 Optical System

A lens focuses the laser beam down into the sample which is enclosed in a temperature-controlled scattering cell surrounded by a refractive index matching liquid. The scattered light is focused onto a PMT at an angle \(\theta\) by another lens. Systems like this are constructed on a precision turntable with a stepper motor, and typically allow experiments to be conducted over a \(10^°–160^°\) angular range.

6.3 Detector System

PMTs are almost universally used as detectors in DLS experiments (Table 3). These should have a low dark count and a high gain since most work is done in

the single photon counting regime. A comparatively new development is the single photon counting mode (SPCM) by EG&G (55) which incorporates an avalanche photo diode (APD), active reset and quenching electronics and a Peltier-type temperature controller in a small package. This author investigated the properties of the APD (supplied then by RCA Canada) in 1985 and found that they were not well suited for DLS applications owing to the lack of active quenching and the lack of an integrated temperature control for the semiconductor junction (unpublished). Brown (56) developed the required circuits and successfully implemented APDs into small fiber-optic-based DLS devices. New SPCMs can replace PMTs in many applications, particularly for wavelengths of more than 680 nm (near infrared).

6.4 The Digital Correlator

The correlator has become the device of choice to generate the raw data in a DLS experiment, although the early experiments mostly employed “wave analyzers” or “spectrum analyzers”. (Today only one commercial instrument (32) still performs DLS particle sizing in the frequency domain by employing a real-time spectrum analyzer.) The basic design of a correlator is really very simple and was originally used at the Royal Radar Establishment, UK (57) (now Defence Evaluation and Research Agency) to recover radar signals that are deeply buried in noise. This instrument was commercialized by (then) Precision Devices, (now) Malvern Instruments (58) in the early 1970s. The ACF is formed by recording the number of photons arriving in each sample time, maintaining a history of this signal over a large range of sample times (time series), multiplying the instantaneous and the delayed signal for a range of time delays \( t_d \) (the “channels”) and accumulating these products. In the past most designs employed a multibit shift register to maintain a record of photon counts, as shown in Figure 4. In modern nonlinear correlators shift registers have been replaced by fast memories, allowing very flexible channel configurations with dynamic ranges that exceed 10 decades of time. Individual design details may be gathered from the manufacturers’ literature.

Figure 5 shows an example of a complete stand-alone DLS-based, commercially available instrument that incorporates all of the above mentioned optics, electronics and data processing.

7 EXAMPLES OF DYNAMIC LIGHT SCATTERING MEASUREMENTS

7.1 Particle Size Distributions

The majority of applications for DLS in particle sizing are the rapid routine measurements of mean sizes in QC work. Manufacturers of latexes, pigments, emulsions, micelles, liposomes, vesicles, sils and silica can track the consistency of the desired particle sizes rapidly and accurately, independent of different operators and different instruments anywhere in the world. Often a bimodal distribution characterizes a sample better and is actually expected from the known chemistry of the sample. In such cases $G(\Gamma)$ will contain two modes that can be separated if their size ratio is at least 1:2 and the relative intensities are similar. Samples that tend to coagulate are easily tracked by DLS. Although the exact size distribution cannot be determined, the first and second moments are very sensitive to any changes in the distribution and give an immediate and accurate response. DLS-based particle sizing is also widely used for biological samples such as bacteria, viruses, proteins, DNA, etc. Many applications are in crystal growth and polymer research. The following few examples illustrate the breadth of DLS-based size measurements.

- Spontaneous vesicle formation in a biological surfactant (ganglioside GM3) was investigated by L. Cantu and M. Corti.\(^{59}\)
- Studies of BSA and lysozyme, very low molecular weight proteins, were conducted by H. Dhadwal et al.\(^{60}\)
- Protein (lysozyme) crystallization was investigated by Mikol et al.\(^{61}\)
- Submicron emulsion systems were measured by Herb et al.\(^{62}\)
- Liposome production is monitored by DLS in QC and research by the Avestin Corp.\(^{63}\)

- B. Weiner\(^{44}\) et al. used a fiber optic backscattering device to observe particle–particle interaction in highly concentrated latex suspension.
- Particle sizing related research on non-ergodic systems have been published by van Megen.\(^{64}\) DLS was applied to the glass phase of nonaqueous suspensions of sterically stabilized colloid spheres.
- A widely used industrial process, hydro metallurgical solvent extraction, was investigated by Neuman\(^{65}\) et al., applying the DLS technique to very small particles in the region of 2 nm.
- Caldwell\(^{66}\) investigated emulsions by employing DLS and sedimentation field flow fractionation (SFFF) methods in a complementary mode. SFFF provides for a high-resolution fractionation of the sample and DLS measures the sizes without the need to know the density of the sample.
- Multiangle particle sizing and its associated data transformation have been investigated by Cummins.\(^{67}\) If the sample is very clean, the multiangle constraint can be a powerful conditioning for the inversion matrix to stabilize the set of $G(\Gamma)$.
- Auweter et al.\(^{68}\) published on-line measurements with a one-fiber backscattering device as early as 1985. Their experiments demonstrated the feasibility of such fiber optics in a hostile environment.

8 COMPARISON WITH OTHER PARTICLE SIZING METHODS

Different techniques yield different “sizes” for the same particles simply because they employ different physics for the measurement. DLS, for example, will easily detect a few large particles among many small ones. Also, the DLS technique is absolute and there are no adjustable parameters available for a “calibration”. Often the term

HDC, hydrodynamic chromatography.
“calibration” is confused with the “validation”. As with any instrument, its proper operation must be verified with known samples, but no adjustments for calibration can be utilized to achieve the “correct” result. This is in contrast to microscopes or “particle counters” for which a calibration must be performed (Table 4).

Dynamic ranges are valid for one measurement without changing optics, capillaries, etc. All the techniques cover at least part of the DLS range of particle sizes: ca. 0.001–3 μm. Measurement times are typical and depend on the breadth of the distribution, absolute size and physical properties of the particles (e.g. density), desired precision, etc. The widely used Fraunhofer diffraction instruments are advertised as covering a size range of as low as 20 nm to several millimeters. These devices actually combine two distinct instruments: one that is based on diffraction theory (low-angle scattering) with \( d^2 \) weighting and one based on Mie scattering with \( d^6 \) weighting. This explains the large dynamic range that is advertised for these instruments but because of the different weighting and low resolution a true merging of the mass distribution is impossible, regardless of the claims in the manufacturers’ literature. Thus comparisons between DLS and “Fraunhofer” sizing results ought to be performed with great caution by carefully evaluating the experimental conditions and examining the mathematical transformations that are required.

9 NEW DEVELOPMENTS

9.1 New Correlator Developments

In the last several years new correlators have become available, which are remarkably compact, have a large dynamic range in delay time and can accommodate many more counts in a given sample time. These developments are a direct result of the availability of more versatile, higher speed and higher density integrated circuits, and novel approaches to the implementation of the autocorrelation operation. Based on designs by K. Schätzell(22,23) the ALV company(69) is developing a correlator with 16 inputs and a minimum sample time of 800 nsec (50 nsec for a single input). Brookhaven(70) is developing a new correlator that incorporates sophisticated multiple digital signal processing (DSP) in real time. Flexible Instruments(71) offers a range of application-specific integrated circuits based correlator boards. Correlators are really nothing more than specialized DSP instruments, regardless of their specific designs. As such the design of these devices benefits from the relentless improvement in the semiconductor industry: higher speed, more integration, lower power, physically smaller and higher gate densities. These new correlators will extend the application of DLS and improve existing applications.

9.2 Solid-state Lasers

These diodes have become reliable and stable enough to be used in routine DLS based measurements. Higher power DPSS lasers are beginning to replace Ar\(^+\) in many installations. Near infrared lasers (>780 nm) at 100 mW and more can be used in combination with APDs(55) and are particularly well suited for efficient coupling into single-mode fiber optics (large wavelength).

9.3 Fiber Optics

Bulk optics are being replaced more and more with fiber-optic devices. Ricka(72) has shown that single-mode fibers have the unique property of acting as spatial filters yielding high ACF intercepts near the theoretical maximum without sacrificing high intensities that are received by the detector. Ongoing developments will improve the efficiency of launching laser beams into single-mode fibers (currently about 40%) and make polarization-preserving filters more widely available.

9.4 New Applications

- Diffusing wave spectroscopy (DWS): in these new experiments by D. Pine and D. Weitz(73) a “length parameter” is calculated from the initial fast decay of the ACF from multiple scattered light, extending DLS applications to samples with higher particle concentrations.
- W. Meyer et al.(74,75) at the National Aeronautics and Space Administration (NASA) designed a promising set-up that employs two detectors and two single mode fibers that are located a tiny distance apart such that the scattered light originates most likely from one speckle. The cross correlation function (CCF) of the signals from the two detectors yields the proper \( D_T \) and hence particle size.
- Based on original work by Dhadwal et al.(76) the commercially available FOQELS instrument from Brookhaven Instruments Corp.(70) utilizes two single-mode fibers at a 155° backscattering angle.
- ALV(69) is currently developing a dual-fiber instrument for backscattering at a 173° angle.

Continuing development of fiber-optic technology will make it possible to construct compact, multiangle light-scattering spectrometers for DLS (and SLS) with no moving parts.
10 CONCLUSION

As any other particle sizing technique, DLS has advantages and disadvantages and it is particularly important to use it strictly within the framework of physical laws, if meaningful results are to be obtained. The following is a short compilation of the advantages and disadvantages of DLS-based particle sizing.

10.1 Disadvantages

- It does not produce a high-resolution histogram of the size distribution.
- Like other nonimaging techniques an equivalent sphere diameter is usually, although not always, assumed. Shape information is not easily obtained.
- When proper measurements are made, the parameters which are most often obtained are the inverse $z$-average moments of the size distribution, not the usually reported parameters of a size distribution.
- Dust can make measurement and interpretation difficult.

10.2 Advantages

- Measurements are fast, from seconds to minutes.
- The technique is absolute, from first principles. Calibration with a known size distribution is not necessary to get answers.
- Very small quantities of sample can be measured.
- Any suitable suspending liquid can be used provided it is nonabsorbing, relatively clear and not too viscous.
- The technique is applicable from about 0.001 to several microns.
- Instrumentation is commercially available for both research and QC measurements with automation including data analysis.
- Although the interpretation of particle size is least ambiguous with a narrow distribution, an effective diameter and polydispersity index are measurable even with broad distributions.

In order to provide an introduction to the DLS technique, the physical basis of the technique and the associated instrumentatation has been discussed. Several new developments in the instrumentation have been described which have the potential for fundamentally changing the way DLS measurements are made and lead to many new applications of the technique. The commercial importance of DLS as a submicrometer particle sizing tool ensures that technological developments will occur rapidly in this field.\(^\text{32,55,58,63,69,70,71,77–79}\)

### LIST OF SYMBOLS

- $a$: Instrument constant
- $A_{\text{coh}}$: Coherence area
- $A_{\text{det}}$: Detector area
- $A/D$: Amplifier/Discriminator
- $A_{\text{Ar}}^+$: Argon Ion laser
- $B$: Baseline of the intensity ACF $G^{(2)}(t_d)$ before normalization
- $B(c)$: Concentration factor
- $c$: Particle concentration
- $\text{cps}$: Photon counts per second
- $g^{(1)}(t_d)$: Normalized correlation coefficient at delay $t_d$ (Field ACF)
- $d$: Particle diameter
- $d_{\text{det}}$: Diameter of the detector area
- $\langle d_n \rangle$: Mean diameter by number
- $d_p$: Distance between particles
- $d_{\text{sr}}$: Diameter of scattering area
- $d_z$: $z$-average diameter (the next higher weighting after mass: intensity)
- $D_T$: Translational diffusion coefficient
- $g^{(1)}(t_d)$: First-order correlation coefficient at delay $t_d$
- $G(\Gamma)$: Line width distribution function
- HeNe: Helium Neon laser
- $\langle I(q) \rangle$: Time averaged intensity at wave vector $q$
- $k_B$: Boltzmann constant
- $K$: Optical constant
- $M$: Particle mass
- $n$: Refractive index
- $N$: Number of particles
- $P(\Theta)$: Particle form factor
- $q$: Wave vector
- $Q$: Polydispersity index
- $R$: Distance between scattering volume and detector
- $t$: Time
- $t_d$: Delay time between multiplication terms for $C(t_d)$
- $T$: Absolute temperature (Kelvin)
- $\Gamma$: Line width of scattered light (radians/sec)
- $\langle \Gamma \rangle$: Average line width
- $\eta(T)$: Viscosity of the medium in which particles are suspended (Poise)
- $\Theta$: Scattering angle
- $\lambda$: Wavelength of light in the suspension medium ($\lambda_0/n$)
- $\lambda_0$: Wavelength of light in vacuo
- $\mu_i$: Moments of a distribution ($i = 1, 2, \ldots$)
- $\tau$: Decay constant for exponential forms of $C(t_d)$; $C(\tau) = C(0)/e$

Sedimentation in Particle Size Analysis

Claus Bernhardt
Technische Universität Bergakademie Freiberg, Germany

1 INTRODUCTION

It is well known that the measuring principle of sedimentation methods is partially based on the fact that it is possible to make conclusions about the geometrical dimensions (size) of particles from knowledge of the speed of their movement in a fluid. Therefore, the temporal and spatial changes in the particle concentration in a sedimenting system provide substantial information on the quantitative distribution of particle sizes. The measurement of such distributions is called sedimentation analysis; it requires the theoretical understanding and experimental handling of the following two phenomena:

- the connection between sedimentation velocity and particle size depending on the material properties of the system and the other conditions in the sedimentation vessel,
- the connection between the concentration distribution of the solid observed after time $t$ and its size distribution. This requires methods that both indicate concentration changes and allow calculation of the distribution from the measured data.

The methods of sedimentation analysis are grouped according to the following fundamental criteria:

- according to the position of particles at the beginning of measurement
  - homogeneous methods: the particles are uniformly distributed over the whole sedimentation space
  - line start methods: the particles in the beginning are concentrated in a thin layer on top of the solid-free medium

- according to the place of quantity measurement
  - incremental methods: the amount (concentration) of solids in a thin suspension layer (measurement level) is measured
  - cumulative methods: the total amount of solids above or below a measurement level is measured

- according to the force field
  - gravitational methods
  - centrifugal methods.

In effect, there are eight groups of sedimentation methods which, however, are not of equal practical significance. Methods widely and frequently used at the moment include the incremental and partially the cumulative methods in a gravitational or centrifugal field.
PARTICLE SIZE ANALYSIS

For incremental methods, the mass or volume distribution are directly measured in the one-layer (suspension) method, and the corresponding frequency distribution is measured in two-layer (line start) methods. In contrast, the mass or volume distribution are obtained for the two-layer scheme in the case of cumulative methods. For a cumulative one-layer scheme, the distribution has to be determined by differentiation on the basis of the cumulative measurement result.

A further subdivision of the sedimentation methods is based on the type of principle for measuring the solids concentration:

- Gravimetric determination (mass)
  - weighing of the solid mass contained in the suspension sample (pipette methods, decanting)
  - weighing of the solid mass sedimented on a balance pan (sedimentation balances)

- Measurement of the absorption of electromagnetic radiation
  - light attenuation (photometric extinction methods)
  - attenuation of γ-radiation

- Measurement of suspension density
  - manometer methods
  - diver methods (areometers, divers)

Again, these principles of measurement are not all of the same importance for the different types of sedimentation analysis. A large number of known methods (several reviews can be found in the literature1–15) can be found in granulometric measurement technology. The following advantages may have played a decisive role in this:

1. Like all classification methods (and unlike the nonfractionating methods), sedimentation analysis gives the proportion of particles that are smaller than the smallest measurable particle size.
2. Very simple and inexpensive devices can be used which can even be built by the user.
3. Frequently measurement is possible without the disturbance of interference to the system.
4. At a higher cost, fast automatic devices can be employed.
5. The range of measurement can be extended below 0.1 µm if a centrifugal field is used.

Disadvantages particularly in comparison with modern nonfractionating methods are:

1. There are numerous subjective and objective sources of error.
2. The maximum particle size is usually approx. 50 µm; larger particles can be measured only in special cases.
3. The time of analysis during which numerous conditions have to be kept constant is relatively long in comparison with modern nonfractionating methods.

The latter problem has been most responsible for the decline in use of a considerable number of previously widespread devices and methods. This is especially the case for methods that do not allow for a decisive reduction in the sedimentation height, such as sedimentation balance, diver, and so on.

In the following chapters we will deal with particle movement in a fluid, dispersion problems and then with some of the techniques of sedimentation analysis.

2 PARTICLE MOVEMENT IN A FLUID AT REST

2.1 Undisturbed Particle Movement

Undisturbed sedimentation takes place if the particles in a fluid of infinite expansion are separated by such distances that any mutual influence can be excluded.

2.1.1 Stationary Movement of Spherical Particles

In the stationary case, a particle moves with constant velocity \( U \) relative to the surrounding medium. There is an equilibrium between the weight \( G_P \) minus buoyancy \( A_P \) and the drag force \( W_P \) exerted on the particle by the medium (fluid), Equation (1):

\[
W_P = G_P - A_P = V_P (\rho_s - \rho_m) g
\]

Furthermore, according to Newton, Equation (2):

\[
W_P = \frac{1}{2} \rho w F_P \rho_m U^2
\]

From Equations (1) and (2), the fundamental equation of stationary particle movement in a fluid is obtained, Equation (3):

\[
U^2 = \frac{2 \Delta \rho g V_P}{\rho w \rho_m F_P}
\]

For spherical particles (Equation 4) with

\[
V_P = \frac{\pi}{6} x^3; \quad F_P = \frac{\pi}{4} x^2
\]
Equations (2) and (3) become Equations (5) and (6)

\[ W_p = \frac{\pi}{8} \rho_m c_W x^2 U^2 \]
(5)

\[ U^2 = \frac{4 \Delta \rho g x}{3 c_W \rho_m} \]
(6)

The particles are usually assumed to be spherical in shape. This, however, leads to a fundamental discrepancy with respect to the real conditions in most cases, because the size of a particle of any shape is described by the dimensions of a solid sphere which has the same hydrodynamic behavior as the particle. It is clear that such an approach is acceptable only as long as the shape of the particle does not change between measurements; otherwise, grain-shape characteristics have to be included in the description of the hydrodynamics of the particle.

For the entire size range, the dependence of the drag coefficient on the sedimentation rate of spheres can be determined only empirically. Some values are collected in Table 1.

The curves are shown in Figure 1, with the Reynolds number, Equation (7)

\[ Re = \frac{\rho_m U x}{\eta} \]
(7)

on the axis of abscissa.

An exact physical description of the dependence \( c_W(Re) \) has so far been impossible because the Navier–Stokes differential equations (see Happel and Brenner,\(^{(17)}\) and Lamb\(^{(18)}\)) can be integrated only if certain terms are neglected, so that the solutions are always true only for a limited range of Re numbers.

By neglecting inertia terms in the Navier–Stokes equations, Stokes\(^{(19)}\) in the middle of 19th century found the formula, Equation (8)

\[ W_{St} = 3\pi \eta x U \]
(8)

for the drag force. This is equivalent to, Equation (9), (see Figure 1)

\[ c_W = \frac{24}{Re} \]
(9)

With Equation (6), this gives the well-known “Stokes equation”, Equation (10)

\[ U = \frac{\Delta \rho g x^2}{18\eta} \]
(10)

However, there are lower and upper limits for using the Stokes equation. If the Reynolds number and the particle size are very small and the latter is of the same order of magnitude as the mean free path of the fluid molecules, Equation (11)

\[ L = \left( \frac{3\eta}{\rho_m} \right)^{1/2} \frac{M_M}{3kTN_L} \]
(11)

one can no longer assume that the fluid is a continuum. These conditions lead to a lower drag force and, consequently, to an increase in the stationary sedimentation velocity.

For liquids, the mean free path \( L \) of the molecules is about \( 10^{-9} \) cm. On the other hand, particles whose size is determined by the Stokes velocity are no smaller than approx. \( 10^{-6} \) cm (0.01 \( \mu \)m) so that the effect can be neglected in liquids. The situation is different with gases. Their mean free path is approx. \( 10^{-5} \) cm under normal conditions, that is the drag force must be corrected. The general type of this so-called “Cunningham correction” is given by Equation (12)

\[ W = \frac{3\pi \eta}{C_L} U \]
(12)

(terms for \( C_L \) see Table 2).
Generally, correction is necessary for particles < 10 µm in air. Without any correction, the measured values \(Q_1(x)\) are shifted in the direction of the coarser range with respect to the actual particle size distribution.

For large Reynolds numbers the empirical drag coefficient is larger than that predicted by Stokes, therefore the settling velocities in sedimentation will be smaller than expected. This means that the measurement values \(Q_1(x)\) are shifted in the direction of smaller sizes. In general, a size error of approx. 1–2% (equivalent to an error in the drag coefficient of approx. 3–5%) can be accepted even for very narrow distributions. Then the upper limit of the acceptable Reynolds numbers is between 0.25 and 0.5 for these values.\(^{(13)}\)

A considerable number of equations have been proposed in the literature to enable further extension towards higher Reynolds numbers.\(^{(13,25)}\) On the whole, they all have the fundamental structure, Equation (13)

\[
c_{w,i} = \frac{24}{Re} B_i
\]

For examples of \(B_i\) see in Table 3.

The value of the maximum permitted Reynolds number \(Re_{\text{max}}\) applies to maximum particle size errors of ±1% and ±2% respectively. They were calculated on the basis of the difference between \(c_w\) according to Equation (13) and empirical \(c_w\) values (Allen,\(^{(16)}\) Bernhardt,\(^{(31)}\) see Table 1). The maximum particle size \(x_{\text{max}}\) can be calculated by, Equation (14)

\[
x_{\text{max}}^3 = \frac{18\eta^2}{\mu m \Delta \rho g} B_i Re_{\text{max}}
\]

Table 3 also shows the case of quartz in water.

Unfortunately, some of the equations (Proudman and Pearson,\(^{(28)}\) Schiller and Naumann\(^{(30)}\)) do not allow for an analytical solution of the sedimentation velocity \(U\) or the particle size \(x\), so that an iteration has to be programmed before they can be used.

On the other hand, in such cases the empirical calculation can possibly be done without an analytical approximation equation.

In 1933 Schiller and Naumann\(^{(30)}\) developed a graphical method which later was improved and modified by several authors.\(^{(32,33)}\) It is based on the calculation of either Equation (15)

\[
c_w Re^2 = \frac{4 \Delta \rho g \rho_{\text{m}} x^3}{3 \eta^2} = \frac{4}{3} A r
\]

or Equation (16)

\[
c_w \frac{Re}{U} = \frac{4 \Delta \rho g \eta}{3 \rho_{\text{m}} U^3} = \frac{4}{3} \frac{1}{L j}
\]

depending on whether the particle size \(x\) or the sedimentation velocity \(U\) is given. These values are points on the empirical curve \(c_w/Re\) (\(c_w Re^2\)) which are represented in Figure 2 (for further values, see e.g. Clift\(^{(25)}\)).

Because of the large error in the graphical method, the following approximation, Equation (17) is useful for a numerical calculation (see Davies\(^{(21)}\)):

\[
Re = 4.1667 \times 10^{-2} K - 2.336 \times 10^{-4} K^2
\]

\[
+ 2.0154 \times 10^{-6} K^3 - 6.9105 \times 10^{-9} K^4
\]

where \(K = c_w Re^2\)

\(\eta, \rho, \mu, \rho_{\text{m}}, x, A, L, j, r, \mu_m\) are symbols for physical constants.
Equation (8) is no longer true and has to be replaced by the formation of the flow. For the drag force, the simple acceleration but also on the conditions prevailing during depends not only on the instantaneous velocity and according to Clift et al.

It fits very well in the range \( Re \leq 4 \) \( (c_wRe^2 \leq 133) \); the drag error remains \( \leq 0.6\% \).\(^{(31)}\)

To calculate \( U \) for a given \( x \) (outside the Stokes range, i.e. for large \( Re \) numbers):

1. Calculate \( c_wRe^2 \) according to Equation (15), take out the \( c_w/Re \) value from Figure 2 and calculate \( U \) by means of transformed Equation (16) or
2. Calculate \( c_wRe^2 \) according to Equation (15), calculate \( Re \) by means of Equation (17) and then \( U \) by means of Equation (7).

2.1.2 Nonstationary Movement of Spherical Particles

If a particle in a fluid is subject to an acceleration, the process is called nonstationary movement. Such a case is given when, in a fluid at rest, the particle is brought from its rest position \((t = 0; \quad v = 0)\) to its terminal velocity of settling \((t = \infty; \quad v = U)\). In contrast to the stationary case, the (inertial) force acting on the particle is now equal to the difference between its weight minus buoyancy and the drag force of the medium, Equation (18)

\[
m_P \frac{dv}{dt} = G_P - A_P - W_P \quad (18)
\]

The first term is the Stokes drag for stationary motion at instantaneous velocity. The second term is the “added mass” or “virtual mass” caused because the acceleration of the particles requires acceleration of the fluid. The third term includes the “Basset history integral” representing past acceleration, where \((t - s)\) is the time elapsed since the past acceleration.\(^{(25)}\)

The substitution of Equation (19) into Equation (18) produces a differential equation with some difficulties for its practical application.\(^{(34)}\)

Therefore the solution without the Basset term is used in most cases:

\[
\frac{v}{U} = 1 - \exp \left\{ -\frac{18\eta}{\rho_s + \rho_m/2} t \right\} \quad (20)
\]

The time \( t_{99} \) for which \( v/U = 0.99 \) is then (without the Basset term):

\[
t_{99} = 0.2558 \frac{\rho_s + \rho_m/2}{\eta} x^2 \quad (21)
\]

This approximation is sufficient for solids in gases \((\rho_s/\rho_m > 1000)\) only. In the case of large solid particles in liquids \((\rho_s/\rho_m < 100)\) the Basset term must not be neglected; according to the calculations of Clift et al.\(^{(25)}\) Equation (22) holds (including the Basset term):

\[
t_{99} \approx 800 \frac{\rho_m x^2}{\eta} \quad (22)
\]

Large particles with sizes near the upper border of the Stokes range need a few seconds to come close to the terminal velocity from the initial quiescent state. As an example, quartz particles with \( x = 0.1 \) mm in water give \( t_{99} = 8 \) s according to Equation (22).

2.1.3 Stationary Movement of Nonspherical Particles

2.1.3.1 Fundamentals

Hydrodynamic concepts not related to a sphere have to be related to a different defined geometric shape, which should apply flexibly to all existing shapes from a very thin plate to a very long rod. Such a shape is the ellipsoid with the half axes \( a, b, c \) for which the equations of motion have long been known.\(^{(17,18,35,36)}\)

For the important borderline cases of the ellipsoid, that is, plates \((a = b > c)\) and rods \((b = c < a)\) Gans\(^{(36)}\) gives complete analytical solutions for the sedimentation of the particles in the direction of either their \( a \)-axis or their \( c \)-axis. For these shape types Equations (23) and (24) hold

\[
U_P = \frac{2}{9} \frac{\Delta \rho g a c}{\eta} R_P \quad \text{(for plates)} \quad (23)
\]

\[
U_R = \frac{2}{9} \frac{\Delta \rho g c^2}{\eta} R_R \quad \text{(for rods)} \quad (24)
\]

The terms for the factors $R_P$ and $R_R$ for both directions $c$ and $a$ can be taken from Table 4.

Table 5 also contains some values of $R_P$ and $R_R$ for the two special sedimentation directions.

For spherical shape ($p = 1$), all $R$ values assume the value 1 so that Equations (23) and (24) become identical with the Stokes formula.

According to Gans\(^{36}\) for very thin plates $p \ll 0.2$ there is an acceptable approximation, Equation (29)

\[ R_{P,c} = \frac{3\pi}{8} = 1.178 \] (29)

from which the well-known formula of the drag force, Equation (30)

\[ W_{P,c} = 16\eta aU \] (30)

is derived\(^{18,37}\). This, however, is true only for thin plates whose large half axis $a$ is in the horizontal plane, and which sediment in the direction of their short half axis $c$ (vertically). Experimental investigations concerning the validity and applicability of these theoretical concepts have frequently been published in the literature\(^{32,33,37–43}\).

The sedimentation directions discussed so far relate to the position of the $a$-axis or $c$-axis of the spheroids in the direction of sedimentation. In reality, however, every particle orientation has the same probability at the beginning of sedimentation. Theoretically, this situation remains unchanged in the range of the creep flow for the whole sedimentation path\(^{17}\).

Figure 3 shows schematically a spheroid, whose $a$-axis is inclined towards the horizontal $x$-axis by the angle $\alpha$.

Dependent on its inclination with respect to the horizontal, forces (not represented) act on the particle in such a way that a resulting velocity $U$ with the horizontal and vertical components $U_x$ and $U_z$ is formed. Equations (31–33) are valid\(^{36,44}\):

\[ U^2 = U_x^2 \sin^2 \alpha + U_z^2 \cos^2 \alpha \] (31)
\[ U_x = (U_a - U_c) \sin \alpha \cos \alpha \] (32)
\[ U_z = U_a \sin^2 \alpha + U_c \cos^2 \alpha \] (33)

$U_a$ and $U_c$ are the velocities in the extreme positions $\alpha = 90^\circ$ and $\alpha = 0^\circ$. Table 6 gives some values of $U_i/U_c$ and $U_a/U_c$ dependent on the angle $\alpha$.

It is evident that the horizontal component $U_x$ can assume considerable values for extreme particle shapes. In most cases, however, the differences between the resultant $U$ and its vertical component $U_z$ are negligible. Experimental investigations of plates and rods dependent on their angular position $\alpha$ have been many attempts to correlate the shape factors defined by the particle geometry and its hydrodynamic behavior (see the overview by Pahl et al.). Wadell and Heywood reported this in great detail. Wadell holds the view that for sedimentation processes, the proportion of the surface area to the volume is the decisive factor. This leads him to the shape factor called sphericity, Equation (40) for plates

$$K_p = \frac{U_z}{U_c} = p^{1/3} \left[ R_{P,a} \sin^2 \alpha + R_{P,c} \cos^2 \alpha \right]$$

(38)

for rods

$$K_R = p^{2/3} \left[ R_{R,a} \sin^2 \alpha + R_{R,c} \cos^2 \alpha \right]$$

(39)

There have been many attempts to correlate the shape factors defined by the particle geometry and its hydrodynamic behavior. For example, Pettyjohn and Christiansen found the empirical relationship between $\psi_{Wa}$ and the shape factor $K$, Equation (41)

$$K = 0.843 \log \left( \frac{\psi_{Wa}}{0.065} \right)$$

(41)

Another shape factor, also defined by Heywood was called the volume coefficient, Equation (42)

$$k = \frac{V_P}{x_F^2}$$

(42)

where $x_F$ is the equivalent projected area diameter.

Heiss and Coull eventually found empirical equations for the shape factor $K$; they also included, in addition to $\psi_{Wa}$, a new factor which was called circularity, Equation (43)

$$\psi_{HC} = \frac{x_V}{x_F}$$

(43)
2.2 Disturbances and Influences on Particle Movement

2.2.1 Apparent Distributions

Numerous influences on the sedimentation motion mean that the true distribution is not measured, only an apparent one. Consequently, a particle system presumed to be monodisperse is then measured as an apparently polydisperse system. Factors contributing to this effect are:

- Factors caused by the particles
  - deviation from the spherical shape
  - Brownian motion of the particles
  - heterogeneity of the solid

- Factors caused by the method
  - limitations of the vessel
  - extension of the measuring gap.

The question of great practical interest is, what distributions are to be measured finally if the starting distribution is already polydisperse? This problem can be solved by the strict application of the “concept of apparent distributions” developed by Bernhardt.\[^{48}\] It allows passage from the monodisperse case to the polydisperse one.

What is the principle of the concept mentioned? The explanation is given in Figure 4.

The upper part of the figure shows the principle of the incremental sedimentation analysis: the solid particles are homogeneously distributed in a vessel at the time \(t = 0\); the solid concentration is constant at every depth \(h\) as shown below. A sensor, situated at a depth \(h_M\), measures the solid concentration there as a function of time. In the ideal case, the highest particle layer of a monodisperse system just reaches the measuring depth \(h_M\) at the time \(t = t_1\). This leads to a concentration jump at this point and the cumulative distribution represents monodispersity exactly. In the real case, however, after \(t_1\) there is a more or less diffuse border near the measuring plane. Consequently, the measured course of concentration is as shown in Figure 4, which results in an apparent polydisperse distribution.

2.2.2 Particle Shape

To estimate the influence of the particle shape on the results of the sedimentation analysis, we assume:

1. The particle system is monodisperse with constant particle shape.
2. It can be described by spheroids as explained above in section 2.1.3 (\(c\) or \(a\) and \(p\) const.).
3. The actual particle orientation does not change during the sedimentation (\(a\) = const.).

In Figure 5(a) such a particle system is schematically represented in its initial state (\(t = 0\)); for the sake of simplicity, particles of the same orientation were arranged within one column.

After a certain period of time \(t = t_1\), the picture becomes similar to that in Figure 5(b): the particles sedimenting in \(a\)-direction have traversed a longer distance than those with a smaller angle (\(a < 90^\circ\)). Therefore, unlike the case of monodisperse spheres, there will be no distinct concentration jump in the depth \(h_M\) (on the measurement level) but there will be a concentration change whose course will be reflected as an apparent particle size distribution \(Q_3(x_S)\) as a result of the measurement. Owing to the equal probability of all
angular positions, Equation (44) holds

\[
Q_3(x_S) = \frac{1}{\pi} \arccos S_{P,R}
\]  

(44)

The apparent Stokes particle size \(x_S\) is calculated by equating \(U_z\) (Equation 33) with Stokes equation. Then, for the two spheroids (plates and rods) an apparent distribution is obtained, Equation (45)

\[
Q_3(x_S) = \frac{1}{\pi} \arccos S_{P,R}
\]  

(45)

where Equations (46–48) apply

\[
S_P = \frac{2(x_S^2/x_a x_c) - R_{P,c} - R_{P,a}}{R_{P,c} - R_{P,a}}
\]  

(46)

\[
S_R = \frac{2(x_S^2/x_c^2) - R_{R,c} - R_{R,a}}{R_{R,c} - R_{R,a}}
\]  

(47)

\[
x_a = 2a; \ x_c = 2c
\]  

(48)

If \(x_S\) is related to the median \(x_{S,50}\) of the distribution, Equations (49) and (50) follows

\[
Q_3 \left( \frac{x_S}{x_{S,50}} \right) = \frac{1}{\pi} \arccos T_{P,R}
\]  

(49)

where

\[
T_P = T_R = \frac{R_c + R_a}{R_c - R_a} \left( \frac{x_S^2}{x_{S,50}^2} - 1 \right)
\]  

(50)

where \(R_a\) and \(R_c\) are according to Equations (25–28).

This distribution is graphically represented in Figure 6 for some values of \(p = x_c/x_a\), starting with the smallest particle size \(x_{S,c}\) (sedimentation in \(c\)-direction; \(\alpha = 0^\circ\)) and ending with a maximum \(x_{S,a}\) (sedimentation in \(a\)-direction; \(\alpha = 90^\circ\)).

For thin plates (\(p < 0.1\)) the width of the apparent distribution can, to a rough approximation, be assumed to be independent of \(p\) for all practical cases. For thin rods (needles, fibers) the width of the distribution becomes larger and larger with decreasing \(p\).

Which effect arises in the case of a polydisperse particle system is of practical interest, meaning for example that \(x_a\) is variable, and \(p\) is constant. Then the apparent distribution is, Equation (51)

\[
Q_3(x_a, x_S) = \frac{1}{\pi} \int_{x_{a,\min}}^{x_{a,\max}} q_3(x_a) \arccos S_{P,R} \, dx_a
\]  

(51)

With Equation (51) we are able to estimate the modifications to apparent distributions determined by sedimentation analysis as a function of the shape factor \(p\) and of the distribution of one of the main axes. In Figure 7 the results of a calculation for plates are given where Equation (51) was numerically integrated using the Gates–Gaudin-Schumann frequency distribution, Equation (52)

\[
q_3(x_a) = \frac{m}{\lambda_{\max}} \left( \frac{x_a}{\lambda_{\max}} \right)^{m-1}
\]  

(52)

It can be seen that the distribution parameter \(m\) (slope of the distribution of \(x_a\)) is maintained in practice for the distributions of \(x_S\) and that with decreasing \(p\) the distributions shift to smaller particle sizes, \(x_S\), by a nearly constant factor. For plates this factor is approximately \(1.21 \times 10^{1/2}\). This behavior means that it is possible to calculate a mean shape factor from a measured apparent size distribution \(Q_3(x_S)\) (by means of sedimentation analysis) and another measured distribution of one main axis (e.g. \(Q_3(x_a)\) by means of image analysis).

The principle shown is also applicable for other kinds of polydispersity (see Bernhardt\(^{(13)}\)).

**Figure 6** Apparent size distribution by shape influence (monodisperse: \(x_a\) or \(x_c\) = constant; constant particle shape: \(p = constant\)). (Reproduced from Bernhardt\(^{(13)}\), Copyright 1994, with kind permission from Kluwer Academic Publishers.)
2.2.3 Brownian Motion

It is well known that the fluid molecules of the dispersion medium are subject to thermal motion whose kinetic energy is transferred to the suspended particles. The impact processes are of a stochastic nature; their amounts and directions do not compensate each other at the particle surface at any given time. This is why the particles themselves are subject to stochastic motion, the so-called Brownian motion, which is reflected both by shifts in the three spatial directions and rotation. The macroscopic appearance of this is described by the concepts of translation and rotation diffusion.

In this section, we shall attempt to assess the effects of translating diffusion taking place during sedimentation on the results of the incremental sedimentation analysis. The rotation diffusion will be neglected since we are also restricting ourselves to spherical particles for which the effects of this type of diffusion on the sedimentation movement can be neglected.\(^\text{(21)}\)

In mathematical terms, the problem is equivalent to the solution of the well-known differential Equation (53)

\[
\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial h^2} - U \frac{\partial c}{\partial h}
\]

with the diffusion coefficient, Equation (54)

\[
D = \frac{kT}{3\pi \eta x}
\]

where the Boltzmann constant \(k = 1.38 \times 10^{-16} \text{ g cm s}^{-2} \text{ K}^{-1}\) and \(c\) is the particle concentration at time \(t\) in depth \(h\).

Solutions for different initial conditions have been found by Mason and Weaver\(^\text{(49)}\) and later by Fürth\(^\text{(50,51)}\) in the mid-1920s. New considerations were made using their results (see Bernhardt\(^\text{(13,31)}\)). The equations for a vessel of finite dimensions (i.e. with a suspension level and with a bottom) are complicated and difficult to treat. Therefore, frequently the more simple case is found in the literature for an infinitely long vessel with a sharp borderline of particles at \(t = 0\). Large differences between the two cases occur if the level of measurement is situated near the limitations (bottom and upper levels, respectively).\(^\text{(13)}\) But if the measurement level is placed close to the middle of the vessel then the simple solution is sufficiently accurate. In this case the apparent distribution of a monodisperse system is given by, Equations (55–57)

\[
Q_3(x_S) = \frac{1}{z} - \phi_0(z)
\]

where

\[
z = \frac{x^2 - x_S^2}{x} xh_M \frac{\pi \Delta \rho g}{12 k T} \frac{1}{2}
\]

\[
\phi_0(z) = \frac{1}{\sqrt{2\pi}} \int_0^z \exp \left\{ -\frac{\zeta^2}{2} \right\} d\zeta
\]

The larger the argument \(z\), the smaller are the effects of the diffusion phenomena on the results of incremental sedimentation analysis, which means that a reduced influence occurs by:

- larger particle size \(x\),
- larger sedimentation height \(h_M\),
- higher acceleration \(g\),
- higher density difference \(\Delta \rho = \rho_s - \rho_m\),
- lower temperature \(T\).

This is illustrated by two examples (see Figure 8).

Figure 8(a) demonstrates the extraordinary importance of the sedimentation path; in spite of a shorter measurement interval, measurements with small \(h_M\) lead to much
SEDIMENTATION IN PARTICLE SIZE ANALYSIS

Figure 8 Apparent distributions of monodisperse particles caused by Brownian motion in the gravity field (quartz in water), according to Equation (57). (Reproduced from Bernhardt,13 Copyright 1994, with kind permission from Kluwer Academic Publishers.)

Figure 9 Measuring errors caused by diffusion/Brownian motion, 1 – according to Chung and Hogg,54–56 2, 3 – according to Allen57 with simultaneous decrease in height \( h_M \) by scanning. (Reproduced from Bernhardt13 Copyright 1994, with kind permission from Kluwer Academic Publishers.)

wider apparent distributions than are found with a large \( h_M \). For modern sedimentation analyzers which measure very narrow distributions in the gravity field, this is a decisive restriction in use. In contrast, working in the centrifugal field is much easier. According to Equation (57), an acceleration of \( b = 100 g \) constant over the sedimentation path produces the same apparent distribution as a one hundred times greater height \( h_M \) or a five times greater size \( x \) in the gravity field (see also Svedberg and Rinde52).

For polydisperse solids with a true frequency distribution \( q_3(x) \), logarithmic normal distributions of different median \( x_{50} \) were used: 1, \( x_{50} = 0.14 \mu m \); 2, \( x_{50} = 0.5 \mu m \); 3, \( x_{50} = 1 \mu m \). In the range \( x < x_{50} \) the error represented \( \Delta Q_3 = Q_3(x_S) - Q_3(x) \) is positive and negative and remains small. On the whole, it has to be said, that polydispersity strongly reduces the effect of diffusion. The reason for this is that there is a certain symmetric concentration distribution of the individual particle sizes, and therefore, because of the integration the effect is only remarkable in so far as the symmetry is incomplete. This also explains why shifts occur in both the fine and the coarse range.

From this point of view, incremental measurements in the gravitational field down to 0.1 \( \mu m \) and in the centrifugal field down to 0.01 \( \mu m \) are the limits down to which measurements of polydisperse solids can be performed with an admissible error.

Further details about the diffusion effect in cumulative suspension methods and in incremental line start methods are summarized by Bernhardt13 and Mason and Weaver.49

2.2.4 Geometry of the Sedimentation Vessel

The influence of the vessel geometry is due to the fact that the particles sediment more slowly in the neighborhood...
of the suspension boundaries (walls, bottom, lid) than at an infinite distance from them.

2.2.4.1 Influence of Walls

According to several authors\(^5\)\(^-\)\(^9\) Equation (59) holds for a sphere situated in a cylindrical sedimentation vessel near the wall:

\[
\frac{U}{U_0} = 1 - \frac{9}{32} \frac{x}{l} 
\]

where \(U_0\) is the undisturbed sedimentation velocity and \(l\) is the distance of the sphere center from the wall.

The same relationship was derived by Lorentz\(^6\)\(^0\) for a sphere sedimenting in parallel to a plane wall. The most modern sedimentation devices are equipped with measuring cells which have two parallel walls a small distance apart (some millimeters). Therefore, the theory of Faxén [cited in Happel and Brenner\(^17\)] for a sphere between two parallel walls is of particular interest.

An useful approximation developed by Oseen [cited in Happel and Brenner\(^17\)] for a random position of the sphere is given by Equation (60)

\[
\frac{U}{U_0} = 1 - \frac{9}{32} \frac{x}{l_1} \left( 1 - \frac{l_1}{L} \right) 
\]

where \(L\) is the distance between the walls and \(l_1\) is the distance of the particle center from one wall.

The question arises how the influence of the wall affects the measured result of the sedimentation analysis. Figure 10 shows the change in sedimentation velocity over the relative distance from the wall. For monodisperse material subjected to an incremental method, the curves also characterize the position at which the solid concentration jumps from 0 to 1.

![Figure 10](image1.png)

**Figure 10** Change in the sedimentation velocity by the influence of the wall for different particle sizes and a wall distance of 0.5 cm.

This concentration distribution leads to an apparent distribution Equation (61)\(^13\)

\[
Q_3(x_S) = 1 - \frac{x^3}{8L x^2 - x_S^2} \left( 1 - \frac{9}{8L x^2 - x_S^2} \right)^{1/2}
\]

In the case of polydisperse materials, Equation (61) has to be integrated for all \(x\). Taking into account that \(c/c_0 = 1\) is already true for particles \(x_P < x_M\) (see Bernhardt\(^13\)) we obtain

\[
Q_3(x_S) = 1 - \int_{x_P}^{x_{\max}} \left( 1 - \frac{9}{8L x^2 - x_S^2} \right)^{1/2} q_3(x) \, dx 
\]

The numerical integration of Equation (62) and the application of a Gates–Gaudin–Schumann distribution (Equation 52) leads to differences with respect to the true distribution, shown in Figure 11.

The difference \(\Delta Q_3 = Q_3(x_S) - Q_3(x)\) usually reaches a measurement error of approx. 2% with sedimentation analyses only for narrow particle size distributions \((m \approx 2)\), and even then only in the narrow and steep range close to the rear end of the distribution.

2.2.4.2 Influence of Horizontal Limitations

Horizontal limitations of suspensions can be either closed/fixed (lid, bottom) or open (free surface). Theories comprising both cases were developed by Brenner, Wakiya and Faxén [cited in Happel and Brenner\(^17\)]. For practical

![Figure 11](image2.png)

**Figure 11** Errors due to influence of wall (for polydisperse material, wall distance 0.5 cm). (Reproduced from Bernhardt\(^13\) Copyright 1994, with kind permission from Kluwer Academic Publishers.)
purposes \((x/h < 0.8)\), the half-empirical approximations can be employed, Equations (63) and (64):

for a closed/fixed limitation:

\[
\frac{U}{U_0} = 1 - 0.55 \frac{x}{h}
\] (63)

for an open limitation (suspension level):

\[
\frac{U}{U_0} = 1 - 0.375 \frac{x}{h}
\] (64)

where \(h\) is the distance of the particle from the limitation.

The changes remain very small and can be neglected for practical purposes, because like other modern instruments no values of \(x/h > 0.01\) are reached. The same is true for the apparent distribution measured by incremental analysis of a monodisperse material in a closed sedimentation vessel, Equation (65):

\[
Q_3(x) = \frac{0.25x/h}{1 + 0.25x/h - x^3/x^2}
\] (65)

### 2.2.5 Other Parameters of Influence

#### 2.2.5.1 Concentration of Solids

For technical reasons, the sedimentation methods require suspensions, whose solids concentration must not fall below a certain minimum value. The influence on the sedimentation velocity is an extraordinarily complex problem essentially based on the following effects:

1. The density and viscosity of the suspension are greater than those of the pure liquid (not demonstrated here).
2. For reasons of continuity, the downward volume flow of solid particles is met by a liquid flow of the same magnitude (back flow).
3. In the vicinity of the sedimenting particle, the velocity field is disturbed leading to an increased exchange of momentum (cluster turbulence).
4. The drag force on the individual particle is reduced in the Stokes range by hydrodynamic interaction with neighboring particles.
5. By physicochemical interactions, the solvate sheath carried by the particle (change of effective particle density and suspension viscosity) and the coagulation during collisions (suspension stability) are influenced decisively.

Table 7 gives a survey of the necessary solids concentration for several sedimentation methods.

<td>1.8</td>
<td>0.3</td>
</tr>
</tbody>
</table>

Some examples of the distribution are represented in Figure 12.

The very small distances below the median for larger solids concentration are the reason for most of the effects described in the following.

![Figure 12](image-url)
Back Flow. Owing to the fluid flow counteracting the downward particle flow, the sedimentation velocity of particles of the same size reduced by the back flow velocity is, Equation (68)\(^{(63)}\)

$$\frac{U}{U_0} = \frac{(1 - c_V)^2}{\eta/\eta_0}$$  \hspace{1cm} (68)

where \(\eta_0\) is the viscosity of the fluid without particles. As a result, the error in particle size \(f_x = 1 - (U/U_0)^{1/2}\) has already reached approx. <7% in the concentration range \(c_V < 3\%\).

Swarm Inhibition. Among all the numerous half-empirical and physically founded models describing the whole phenomenon of swarm inhibition (including back flow and swarm turbulence), only that proposed by Bauer and Thiele\(^{(64)}\) will be mentioned here. For the case of a monodisperse solid, Equation (69) holds

$$\frac{U}{U_0} = (1 - c_V) \left( 1 + \frac{c_V}{(1 - c_V)^2} \right) \times \frac{1.05}{\sqrt{1 + (\pi/12c_V)^2 - 0.5}} \right)^{-1}$$  \hspace{1cm} (69)

Now, \(f_x = 1 - (U/U_0)^{1/2}\) becomes <9% for \(c_V < 3\%\). The influence is much stronger if the solid is polydisperse and if the analyzed particles are very small.

Hydrodynamic Interaction. The hydrodynamic interactions between two sedimenting spheres of the same size lead to a reduction in the drag force, for which a theory was developed by Happel and Brenner.\(^{(17)}\)

The velocity ratio \(U_2/U\) is approximately given by Equation (70)

$$\frac{U_2}{U} = 1 + \frac{3x}{8} \left( 1 + \cos^2 \beta \right) = 1 + \frac{3}{8} \left( 1 + \cos^2 \beta \right)$$  \hspace{1cm} (70)

\(\beta\) is the angle between the sedimentation direction and the line connecting the sphere centers. According to Equation (70) the sedimentation velocity continuously increases with increasing solids concentration. Kaye and Boardman\(^{(65)}\) and Johne,\(^{(66)}\) however, have empirically found that this is true only up to a certain solids concentration, above which the swarm inhibition prevails. Johne’s result, the average velocity of individual spheres related to their Stokes velocity, is shown in Figure 13.

Below \(c_V = 10^{-4}\) the solids concentration is practically without influence on the particle movement. In the immediate vicinity of \(c_V = 10^{-2}\), a velocity maximum forms which can be three times higher than the Stokes velocity. As shown by Koglin,\(^{(58)}\) the phenomenon cannot be explained simply by the statistical arrangement of the particles and their hydrodynamic interaction plus swarm inhibition. In addition, the formation of complexes of particles (clusters), whose dimensions and sedimentation velocities grow with increasing sedimentation path and time, has to be assumed.\(^{(67)}\) Furthermore, the size of these complexes is statistically distributed in the suspension so that the sedimentation velocity itself has a distribution. The mean value of this distribution (see Figure 13) strongly depends on both the particle size distribution and the particle shape distribution as well as on other physical parameters of the sedimenting solid.\(^{(58,68)}\) The velocity maximum is lower, the wider the size distribution. Deviations from sphericity reduce the height of the maximum and simultaneously shift it towards lower solids concentrations.\(^{(1–12)}\)

For light optical methods, sedimentation balances and usual pipette methods (with restrictions), the concentration of solids can normally be kept sufficiently low in practice to exclude the influence described. Other methods such as X-ray absorption reach the critical concentration range around \(c_V = 0.01\) for various substances (silicates etc.). In this case, the measurement of narrowly classified material, for example, can yield a clear shift to coarser results in comparison to other methods.\(^{(13)}\)

2.2.5.2 Convection Flows Convection flows occur whenever a suspension of higher density is situated beside or above a suspension of lower density. According to Koglin, Alex and Leschonski\(^{(1–12)}\) the following are at least some of the reasons:

1. The sedimentation vessel does not have exactly vertical walls.
2. In the sedimentation vessel there are inserts (e.g. pipette or other bodies).
3. There are local temperature differences in the suspension caused by fast or inhomogeneous heating (e.g. solar heat radiation) or cooling (e.g. by evaporation at the suspension surface).

While the causes 1 and 2 can usually be overcome by improved design, this is not so easy for cause 3. According to Rumpf and Alex a change of temperature of ±1 K per analysis and 0.01 K min⁻¹ should not be exceeded in a pipette device if the lower limit of measurement is 1 µm. It is difficult always to comply with the latter requirement even with good thermostats. Moreover, particularly in this field the commercially available measurement equipment very often does not meet these requirements.

Convection flows of a different type occur at the beginning of the analysis when a uniform distribution of the solid has to be achieved for suspension methods by stirring or shaking. The decay times observed with water were between 20 and 120 s dependent on the vessel geometry.

In line start methods, a suspension layer is positioned on top of a solid-free liquid at the beginning. When the solids concentration exceeds a certain value, density convection flows occur in the form of streaks, a phenomenon to which Alex et al. have drawn attention so vividly particularly in the case of centrifugal methods. The critical solids concentration at which this process begins is approx. 0.01 vol% according to investigations by Alex et al. This is an amount which is normally not sufficient to measure the mass proportions with satisfactory reliability (except light optical methods).

2.2.5.3 Hydrate Sheath For most particle systems it has to be assumed that a solvate (or in the special case of water, hydrate) sheath is formed, caused by the interaction between the electrically charged particle surface and the molecules of the liquid. This hydrate sheath is carried with the moving particle, with its thickness \( D_H \) depending on the equilibrium between the attraction forces and the flow forces. To estimate the influence of this phenomenon on particle motion, only the change in the effective particle density during sedimentation is taken into account. For spherical particles Equation (71) holds

\[
\frac{\Delta \rho^*}{\Delta \rho} = \frac{x^3}{(x + 2D_H)^3} = \left(1 + \frac{2D_H}{x}\right)^{-3}
\] (71)

Then, the error in the particle size is, Equation (72)

\[
f_x = 1 - \left(\frac{\Delta \rho^*}{\Delta \rho}\right)^{1/2} = 1 - \left(1 + \frac{2D_H}{x}\right)^{-3/2}
\] (72)

The difficulty in such an estimation has to do with the fact that the exact density of the hydrate sheath \( \rho_H \) is not known. As a first approximation we have to assume that \( \rho_H = \rho_m \).

For water a thickness of 3 nm equals approx. 10 molecular layers. Using this value it is evident that for particles >1 µm, the error in the particle size does not exceed 1%, and for particles > 0.2 µm does not exceed 5%. Owing to the lower density of the particles, the distribution curve \( Q_3(x) \) is shifted towards greater fineness.

3 DISPERSION OF SOLIDS IN LIQUIDS

3.1 Introduction and Problems

For particle size analysis by sedimentation a suspension with a defined and constant dispersion state is an essential precondition. In many cases it is very difficult if not impossible to fulfil this precondition in a simple way, since the available information on the complex physicochemical conditions and their mutual interaction is not complete and can be extended only by extensive and partly empirical investigations. Furthermore, in many cases it is impossible to find a satisfactory answer to the question of the desirable dispersion state, which is dependent on the aim of measurement. Ideally, the following requirements would have to be met:

1. The solid particles exist in the suspension individually, i.e. free of agglomerates.
2. The dispersion state shall not be modified in any measurable way during the analysis.

Of course, the transition from separate particles to agglomerates is fluid for different solids, but even in spite of this, the analysis of real powder-type solids will always be at a greater or lesser distance from these ideal conditions.

Incomplete dispersion is often connected with a poor reproducibility of results, so that the decisive factor in sample preparation is to meet the above requirements as closely as possible and simultaneously to measure the state of the system investigated. If a dry powder is to be used for the preparation of a suspension for granulometric analysis, an agglomeration of the primary particles usually has to be expected dependent on the material properties and the conditions during manufacture and storage. The following binding mechanisms play a role:

- binding by adhesion forces between the particles
- binding by wetting liquids of low viscosity
- binding by highly viscous liquids
Dispersion has the task of counteracting these forces by physicochemical and mechanical means to such a degree that the particles will eventually exist individually (i.e. agglomerate-free) and will not change this state in the course of the analysis. For this, certain basic mechanisms are required which can be reduced to the following three fundamental processes:

1. wetting of the solid particles by the liquid
2. desagglomeration of the particle agglomerates
3. stabilization of the suspension or prevention of renewed agglomeration.

The control of the wetting processes only allows the adhesion forces to be modified between the particles and the binding forces produced by liquids in the intermediate capillaries to be partially modified. The methods of desagglomeration should have an effect on all binding forces. Finally, most stabilization is achieved by modifying the interaction forces between the particles.

In spite of their extraordinarily wide range, the methods used to influence and control these processes can be reduced to the following tasks:

1. selection of a suitable liquid (suspending agent)
2. selection of the type and concentration of a suitable (interface active) aid (dispersant),
3. selection of the type and duration of mechanical preparation for dispersion.

In addition to its role in creating favorable conditions for wetting, desagglomeration and stabilization, the liquid medium has to meet several other requirements; these are (according to Irani and Callis\(^\text{74}\) and Joglekar and Marathe\(^\text{75}\)):

1. The solid must not dissolve or chemically be altered under the influence of the liquid, it must neither swell nor shrink.
2. Density and viscosity of the liquid have to be adapted to the solid density, maximum particle size and other parameters of the solid in such a way that measurement takes place at sedimentation velocities which are neither too high nor too low.
3. It has to be possible to render the liquid bubble-free.
4. The liquid should have a vapor pressure as low as possible.
5. The liquid has to be nontoxic, inexpensive and easily available.

The fundamentals of the mentioned physicochemical and physical problems (wetting, particle/particle attraction and repulsion etc.) cannot be treated here in detail. For further information the reader may refer to some well-known monographs\(^{24,76–81}\) and overviews.\(^{13,82–84}\)

### 3.2 Stabilization of Suspensions

In many cases the so-called DLVO theory (Deryaguin, Landau, Verwey and Overbeck) is a useful tool for solving dispersion problems, particularly the stabilization of suspensions. The total interaction energy between two solid particles can be written as the sum of the electrostatic repulsion, the van der Waals attraction and the steric repulsion, Equation (73)

\[
V(h) = V_e(h) + V_A(h) + V_{Ster}
\]  

The theoretical fundamentals were developed by Deryaguin, Landau, Verwey and Overbeck; originally, the theory referred only to the combination of electrostatic and van der Waals interaction. Under these conditions they found a principal curve of \(V(h)\), represented in Figure 14.

When two particles approach each other from a large distance, they proceed through the range of relatively small attraction energies called secondary minima. If these are greater than the collision energy of the particles,
agglomeration takes place then. Since it is impossible to destroy the agglomerates mechanically during sedimentation analysis, conditions have to be found under which the secondary minimum is as small as possible or disappears altogether. This is the case for high interfacial potentials or (preferably) large thicknesses of the double layer and small van der Waals attraction energies.

In these cases, the repulsion energy barrier is so high that agglomeration is possible only for very high-energy collisions of the particles. In this case, the particles adhere to each other in the primary minimum, forming relatively stable agglomerates. However, if the maximum repulsion energy is always greater than the collision energy, the suspension will be stable.

The opposite case, that is, the complete absence of repulsion energies (e.g. for small potentials and small double layer thickness) leads to agglomeration in every case of collision (fast coagulation).

Therefore, in addition to wetting and desagglomeration, the stability of the suspension over the time required for analysis is a decisive problem in the granulometric analysis of suspended particles.

Now, it has to be asked which changes in the number of particles caused by coagulation during sedimentation are within the error range of the analysis data. The results of Bernhardt[85] provide some information on this. Thus, it is fully possible for slowly coagulating systems to meet sedimentation conditions which limit the resulting error. An effective way is the use of minimum solids concentrations or sedimentation times that are as short as possible (low-sedimentation heights).

Modern devices sometimes have sedimentation heights under 0.1 mm; it can be expected that these can be used even for very unfavorable stability conditions, provided, of course, that the time for the other stages of suspension preparation can be kept short.

To give the reader a better overview, some conclusions will be made on the basis of the above statements (see also Bernhardt[13]).

Dispersion in liquids has the following objectives:

1. Spontaneous wetting as complete as possible
   - General aim:
     - high-wetting energy,
     - low-contact angle;
   - Solution:
     - low-interfacial tension liquid/gas by wetting agents,
     - low-interfacial tension solid/liquid by hydrophilizing agents.

2. High electrostatic repulsion energy
   - General aim:
     - high-interfacial potential,
     - great thickness of double layer at low-ionic strength;
   - Solution:
     - polar liquids (high-dielectric constant),
     - use of potential-controlling ions,
     - use of polyelectrolytes for adsorption in the Stern layer.

3. Low van der Waals attraction energy
   - General aim:
     - small difference in Hamaker constants of solid and liquid,
     - large particle distance.
   - Solution:
     - selection of suitable liquids,
     - masking of solid surface by adsorption layer with Hamaker constant similar to that of liquid,
     - adsorption of big molecules or small solid particles for steric repulsion,
     - low-solids concentration.

4. High-repulsion barrier and low-secondary energy minimum
   - same as 2 and 3.

5. Low probability of agglomeration at collision
   - General aim:
     - same as 2 and 3,
     - low-kinetic energy of particles;
   - Solution:
     - same as 2 and 3,
     - high viscosity of the fluid.

6. Low collision probability
   - General aim and solution:
     - low kinetic energy,
     - low solids concentration,
     - short duration of measurement.
It is obvious that the above recommendations are not a recipe for all cases; in many cases, they are not compatible with each other (this has not been described in detail), and they do not guarantee successful dispersion.

The overview shows that good dispersion depends on a very large complex of influencing factors acting together as well as against each other. For many solids, particularly if they are contaminated or heterogeneous, an empirical approach cannot be avoided. There are many examples of this in the literature. Appendix 1 gives an overview of liquids and dispersion aids for sedimentation analysis on the basis of a previous work.$^{(13, 84)}$

Of course, all these data are just recommendations which do not exempt the user from the obligation of informing him or herself on the effectiveness of dispersion techniques, and to test further materials and techniques.

### 3.3 Desagglomeration Methods

Mechanical processes have to be used in most cases of suspension pretreatment, to support or initiate the physicochemical phenomena or to destroy the agglomerates originally present in the system to allow stabilization measures to be come effective. The most important methods will be described briefly.

#### 3.3.1 Dry Sieving

The dry powder is sieved through a test sieve of suitable mesh (e.g., 40 μm) using a brush or similar mechanical aid. The coarse agglomerates are destroyed by this treatment to a degree sufficient for the successful application of other methods (such as ultrasound) for complete desagglomeration. At the same time, the maximum particle size of the system to be analyzed is reduced to a value that can still be reliably measured. This method is preferable in comparison with comminution in a mortar to a value that can still be reliably measured. This method is the possibility of estimating the forces attacking the particle agglomerates in good approximation.

#### 3.3.2 Treatment in Plastic State

In the method described by Allen$^{(16)}$ and Irani and Callis,$^{(74)}$ the powder sample is put on a glass plate or a very flat vessel after which a small amount of water is added, producing a plastic mixture. This is kneaded for some minutes with a suitable spatula. Then, a proper suspension is produced from this material. This method is used if coarser agglomerates must be destroyed with caution or if the material cannot be wetted with ease.

#### 3.3.3 Deaeration of the Solid

For a very fine and/or barely wettable solid, it often makes sense to remove the included air. The following methods are recommended for the production of a sufficiently deaerated suspension:

- addition of liquid to powder in vacuum
- stirring of suspension in vacuum
- boiling of suspension
- treatment of suspension in a laboratory ball mill (without pebbles).

These measures also destroy agglomerates.

#### 3.3.4 Treatment in a Turbulent Shear Field

The simple manual or machine shaking of a suspension in a closed vessel has only a slight desagglomerating effect, because the agglomerate strengths exceed the stress during shaking in most cases. Another possible treatment is stirring. Its use is recommended primarily for cases where wetting is difficult; however, it also contributes to agglomerate destruction to a limited extent.

In this context, the investigations by Nagel and Kürten$^{(86)}$ are of special interest; here, the agglomerate strengths estimated by Rumpf and Herrmann$^{(73)}$ are compared with stress calculated for the shear field. For possible technical values of power dissipation density between $10^3$ and $10^4$ kW m$^{-3}$, only particle agglomerates $>10 \mu m$ can be destroyed if there is only van der Waals binding; in the case of sinter bridges the particles must be $>100 \mu m$. This was confirmed experimentally$^{(86)}$ and is in agreement with practical experience.$^{(87)}$

Finally, another effective method of desagglomeration is the turbulent flow of an annular shear slot. The advantage of this method is the possibility of estimating the forces attacking the particle agglomerates in good approximation.$^{(98, 89)}$

#### 3.3.5 Ultrasonic Treatment

In view of the limited desagglomeration by stirring for small agglomerates, treatment in the ultrasonic field is of special importance for suspension preparation for granulometric analysis. The mechanism of the processes involved has not yet been completely clarified; however, there is general agreement that cavitation is a prerequisite for desagglomeration.

In the ultrasonic field, cavitation is provoked by tensile stresses produced by the acoustical pressure. At first, small cavities (cavitation bubbles) form in the liquid when the so-called cavitation threshold is reached, which grow to a maximum size under oscillations and then collapse very rapidly. In real liquids containing solid particles the cavitation produces complex changes in diverse physical properties which lead to the damping of the ultrasound in the cavitation zone (see also Šutilov$^{(90)}$) and, thus, a reduction of the cavitation
pressure. With increasing sound frequency, the sound energy producing the necessary cavitation increases. For dispersion purposes, frequencies between 20 and 40 Hz for which the necessary acoustical pressures are guaranteed as well are generally used. An increase in the external pressure and liquid temperature improves the effectiveness of ultrasound.\(^{87,90}\) It is often indicated that, unlike other mechanical destruction methods, ultrasound has an eroding effect,\(^{91}\) that is, the primary particles are removed from the agglomerates starting at the surface.

Practical ultrasonic treatment of a suspension for granulometric analysis is usually carried out using two principles:

Principle (a) uses a commercial ultrasound washing device. The suspension vessel is put or suspended in a water bath and irradiated by an ultrasound source fastened to the bottom of the bath. Because of the low-ultrasound intensity, the treatment usually requires a long time to attain the required state of dispersion. In spite of this, the method is widely used in view of its simplicity.\(^{13}\)

In principle (b), the suspension in the vessel is irradiated directly by a sonotrode. Modern commercial devices usually have a fixed frequency; their intensity can be selected (specific power up to approx. 500 W cm\(^{-2}\)). This allows the duration of treatment to be reduced to a few minutes. Intensities between 100 and 200 W cm\(^{-2}\) are usually sufficient.

The dispersing effect of ultrasound decreases with increasing solids concentration, it can be increased in the presence of surfactants. In the most unfavorable cases, even coagulation can occur.\(^{92–94}\)

In some studies the combination of ultrasound with another type of mechanical pretreatment reduces the essential time or provides a higher degree of dispersion.\(^{45,95}\) Davies et al.\(^{87}\) found that ultrasound is most effective for the destruction of small agglomerates while high-speed stirring is best for destroying large agglomerates.

A question always asked in the framework of such investigations is whether ultrasonic treatment destroys the primary particles forming the agglomerates. It is known\(^{91}\) that ultrasound can destroy structures such as the solid bridges between the particles. Davies et al.\(^{87}\) observed changes in the surface roughness of particles > 5 \(\mu\)m.

According to Gärtner,\(^{96}\) particle destruction at the weak connections also has to be expected for precipitation products whose particles consist of several primary crystallites. The newly formed primary crystallites, however, do not show a tendency towards further decomposition.

A remarkable reduction in the particle size was observed for solids with a pronounced anisotropy of cleavability; examples are chrysotile asbestos\(^{97}\) or talcum.\(^{47}\) Thus, it can be assumed that most substances (with the exception of those with extreme properties) are not comminuted by ultrasound.

### 3.4 Characterization of the Dispersion State and the Dispersion Capacity

If the task is to produce a suspension of maximum dispersion for a particle size analysis, it must first be possible to characterize the current degree of dispersion. At the same time, information is needed on possible changes in the physicochemical and mechanical methods with the aim of improving the current degree of dispersion. For this reason, apart from methods for the characterization of the dispersion degree this section will include methods in which the measured parameter has a connection with the dispersion capacity of the solid and from which further information on dispersion measures can be derived (liquid, dispersion aid, parameters of mechanical treatment).

#### 3.4.1 Measurement of Wettability

For the measurement of the wettability the following methods are known:

- measurement of wetting heat
- measurement of adsorption isotherms
- measurement of the contact angle.

Their application to powder-type substances presupposes the availability of the necessary measurement equipment. On the other hand, extensive wetting problems are instantly noticed as an obstacle to suspension preparation that cannot be circumvented. In the case of an insufficient degree of dispersion, insufficient wetting should always be looked upon as a possible reason.

#### 3.4.2 Rheologic Tests

Flow characteristics and dispersion degree are connected in a way that in most cases is specific to the given material. In general, the flowability is best at maximum dispersion. The exact determination of the rheologic characteristics requires measurement equipment (such as rotation viscosimeters) which is not always available. Therefore, such measurements will be done only in special cases; Joglekar and Marathe\(^{75}\) recommend them for sedimentation analysis of clay suspensions.

In the case of a fast method also mentioned by Joglekar and Marathe\(^{75}\) a small amount of suspension is placed on an inclined glass plate. Well-dispersed systems form a smooth uniform layer when flowing down, whereas flocculated suspensions produce a layer in stripes with a heterogeneous lumpy appearance.
Good characterization of the material behavior involves determination of the smear point (beginning of plastic behavior) and the flow point which can be done by relatively simple means.\textsuperscript{(16,74,75)} For this, the dry powder is put into a small vessel (a few grams), and the liquid is added slowly from a burette while the powder is stirred with a spatula or glass rod. The amount of liquid consumed up to the smear point and the flow point is read. The smaller the difference between these two values, the better the dispersion capacity.

3.4.3 Microscopic Analysis

A simple microscopic assessment normally provides little more than qualitative information on the type of liquid and additive and the effect of the mechanical pretreatment.\textsuperscript{(74,75)} A droplet from the ready suspension is brought to the microscope slide. This provides an immediate impression of the analyzed system, its dispersion state and its tendency towards coagulation.

3.4.4 Sedimentation Test

Sedimentation tests in suitable standard laboratory vessels (test tubes, small gas jars) provide a simple means of assessing the dispersion state prior to the proper analysis.\textsuperscript{(74,75)} The suspension is prepared with the same solids concentration as for the analysis; only the type and concentration of the dispersion aid is normally varied. All vessels are installed for the observation of the sedimentation process after uniform pretreatment of the suspension. Good dispersion is reflected by stronger turbidity after a certain time. Even small differences can be recognized by comparison with the neighboring vessels.

After a sufficient time it is possible to determine the volume of solids sedimented on the bottom of the suspension vessel. This sediment volume is smaller, the higher the degree of dispersion. Agglomerated systems form loose sediments with a high content of liquid equivalent to a large sediment volume.

For the example a silicon nitride suspension (see Figure 15) shows the dependence of the sediment volume $V_S$ on the pH-value of the suspension compared with electrophoretically determined $\zeta$-potentials. As expected, high $\zeta$-potentials lead to small sediment volumes and low $\zeta$-potentials lead to high sediment volumes. Therefore, granulometric analysis without problems is expected either for high or low pH values, since these are equivalent to maximum desagglomeration and maximum suspension stability. For a further improvement of this method see Hirosue et al.\textsuperscript{(98)}

3.4.5 Photometric Measurement

According to several authors,\textsuperscript{(16,45,75,92,95,99)} photometric turbidity measurement is carried out dependent on time on a suspension kept in motion (without sedimentation) and with simultaneous mechanical treatment (ultrasound, stirring) and variation of the type and concentration of the dispersion aid. Koglin\textsuperscript{(95)} recommends an optical small-angle scheme measuring the attenuation of white light traversing the suspension in a forward direction. If the Lambert–Beer law is valid he proposed that the agglomeration degree $\beta$ of a suspension be defined as follows, Equation (74):

$$\beta = 1 - \frac{\ln T}{\ln I_{\text{min}}} = \frac{\ln(I_{\text{min}}/I)}{\ln(I_{\text{min}}/I_{\infty})}$$  \hspace{1cm} (74)

where $I$ is the light intensity, $I_{\infty}$ is $I$ for a solid free liquid, $I_{\text{min}}$ is $I$ for an agglomerated system.

For the interpretation of the effect of measurement, the fact that both the particle size distribution and the value of the extinction function $K(x)$ (see section 4.2.1) change must be taken into account. Koglin\textsuperscript{(95)} therefore restricts the use of the method to particles $x > 1 \mu$m. However, his investigations have shown that the influence of all means of dispersion are very well reflected, and procedures for the further treatment of the suspension can be selected very well.
For very high solids concentrations ($c_V > 1\%$) it is possible that measurable transmissions are achieved only for very thin cuvets. In this case, however, the scattered light intensity occurring under a certain angle can be measured and its changes can be followed. This can be done easily for some commercial types of equipment.

Another version of this method is the approach described by Joglekar and Marathe\(^{(75)}\) and Süß and Hantke\(^{(92)}\) according to which the photoextinction method is employed for surface determination. By comparison with surface values determined by other methods, conclusions are made with respect to the degree of dispersion.

### 3.4.6 Zeta Potential Measurement

A zeta potential measurement provides information on the charging state at the solid/liquid phase boundary. If the zeta-potential and its dependence on pH or other charge generating ions are known then in most cases it is possible to find conditions with maximum repulsion energies between the particles. The first application of zeta-potential measurements for the purposes of particle size analysis is described by Bernhardt.\(^{(85)}\)

Experimental determination of the zeta-potential requires special measurement equipment which cannot be described here in detail (see Hiemenz\(^{(77)}\) and Stauff\(^{(54)}\)). Comprehensive measurements of a wide range of materials are documented by Hunter\(^{(78)}\) and Ney\(^{(79)}\) which are available if needed. In such a case, however, it appears to make sense to analyze the dispersion conditions of the material system in question at least on the basis of a second independent quantity (see also Figure 15).

### 3.4.7 Particle Size Analysis

When investigating the influence of the degree of agglomeration on the granulometric result it is recommended that the granulometric method itself be used for the preliminary assessment and to change the conditions of pretreatment until the results of measurement remain constant. However, this requires sufficiently fast measurement, which only modern automatic devices are capable of in sedimentation analysis. On the other hand, it is of great advantage to have available the complete particle size distribution for a comprehensive assessment of the agglomeration state.

In the literature there are two main characteristics for this:

1. degree of agglomeration $\alpha$ (=1 for complete agglomeration, =0 for complete dispersion)

2. degree of dispersion/desagglomeration $\beta$ (=1 for complete desagglomeration, =0 for complete agglomeration).

The essential problem of all the different degrees of agglomeration is that the extreme points (0 and 1) are unknown. Instead we have to use the state in which we start the dispersion experiment or in which we finish it. Table 8 gives some examples of definitions for $\alpha$ and $\beta$, in which only “complete dispersion” is used (characterized by the primary particle).

Which characteristic is suitable for a certain purpose must be decided by the user in each case.

### 3.4.8 Comparison of Methods for Dispersion Control

Table 9 gives an overview of all the above statements about the suitability of the described methods for dispersion control. It must not be forgotten that the classification as suitable, conditional or barely suitable and not suitable is subjective and may depend on the accuracy of the information required.

Nonetheless, the overview provides the correct impression that in the normal case only a few methods are suitable for the solution of all four problems of suspension control.

preparation and that there are only a few methods that allow characterization of the type and duration of mechanical pretreatment.

In conclusion, it follows that no absolute rules can be given for the use of the methods and that it makes sense to consider a combination of several methods on the basis of an assessment of costs and desired effects.

4 SEDIMENTATION METHODS

4.1 Brief Historical View

The development of sedimentation methods began with the soil analyses which have been extensively performed since the middle of the 19th century in which fractions of a certain fineness had to be determined. Because the sample material was elutriated in water, this was called elutriation analysis (Geßner, 1931), a name which was used for most diverse methods for a long time.

A further line of development originates from colloid chemistry which developed rapidly at the beginning of the 20th century (Ostwald 1911 and von Hahn 1928). Apart from appropriate elutriation methods, cumulative methods in all their versions played a decisive role up to the first third of the 20th century. The application of Stokes' equation to sedimentation analysis was a decisive development at that time.

Decanting was abandoned at that time, and various automation or continuous methods of measurement were introduced (sedimentation balance according to Odén 1915, pressure difference method according to Wiegnner 1918). Centrifuges were first used around 1923 by Svedberg and Nichols leading to both time reduction and an extension in the range of the finer fractions.

In the decade between 1920 and 1930, incremental (pipette) methods were invented almost simultaneously and independently by Robinson (1922), Jennings et al., Krauss (1923), Köhn (1928) and, finally, Andreasen (1928). Other incremental methods were those using area meters (Bouyoucos 1927) and later diving apparatus (Berg 1941).

After World War II, incremental methods with contact-free measurement of reasonable quantities by the attenuation of light or γ-radiation were used, and centrifuges were employed to this end. Only this allowed a drastic reduction of the sedimentation height down to fractions of 1 mm which also decreased the time requirements, so that sedimentation analysis remained an alternative and, in many cases, an indispensable granulometric method.

4.2 Gravitational Methods

4.2.1 Incremental Suspension Methods

4.2.1.1 Principle and Fundamentals

For this measurement principle, there is a homogeneously mixed suspension at the beginning of the analysis \((t = 0)\) so that the overall concentration \(c_0\) prevails in every part of the sedimentation vessel. In Figure 16(a) the initial situation is represented so that the individual particle sizes are arranged beside each other.

After time \(t > 0\), there will be a state which is described by Figure 16(b). One portion of the particles has sedimented on the bottom – more large ones than small ones in view of the former's higher sedimentation velocity. Thus, the upper concentration limits of the particles still sedimenting are at different heights in the sedimentation vessel in the order of their size. Size \(x\) has only just reached height \(h\). Here, in the ideal case we measure the solids concentration \(c(h, t)\) in a differential

![Figure 16 Principle of incremental suspension methods. (a) \(t = 0\), (b) \(t > 0\).](image-url)
thin layer after time \( t \). For this, Equation (75) evidently holds

\[
c(h, t) = c_0 \int_0^{x_t} q_3(x) \, dx
\]

(75)

from which follows Equation (76)

\[
Q_3(x_t) = \frac{c(h, t)}{c_0}
\]

(76)

This is the fundamental relationship on which the method is based.

Deviations from the ideal case were described in section 2.2 as far as they influence the settling velocity. Moreover two further problems appear:

1. the finite extension of the measuring gap
2. the heterogeneity of the solid material.

The simple Equation (76) is valid only if the solids concentration is measured as a function of time in a measuring plane. In practice, however, there is always a measuring volume, since both the entrance slit and the exit slit of the measuring radiation have a finite extension \( \Delta h \) (see also Figures 4 and 16). The apparent distribution of a monodisperse material can be calculated by Equation (77):\(^{(13)}\)

\[
Q_3(x_S) = \frac{1}{2} \left( 1 - \frac{h_M}{\Delta h} \left( \frac{x^2}{x_S^2} - 1 \right) \right)
\]

and those of polydisperse material by Equation (78)

\[
Q_3(x_S) = \frac{x_{\text{max}}}{2} \left( \frac{h_M}{\Delta h} \left( \frac{x^2}{x_S^2} - 1 \right) \right) q_3(x) \, dx
\]

\[
+ \frac{x_{\text{min}}}{2} q_3(x) \, dx
\]

(78)

with the integration limits: \( x_{\text{max}} = x_S(1 + \Delta h/2)^{1/2} \) and \( x_{\text{min}} = x_S(1 - \Delta h/2)^{1/2} \).

Using a Gates–Gaudin–Schumann distribution for \( q_3(x) \) (Equation 52) it is possible to integrate Equation (78) analytically and calculate the differences between the true distribution and the apparent one.\(^{(13)}\) In Figure 17 some examples of the error, Equation (79)

\[
f(x_S) = \frac{Q_3(x_S) - Q_3(x_{\text{max}})}{Q_3(x)} \text{ in } \%
\]

(79)

are represented for different distribution parameters \( m \).

The error attains values considerably greater than 1% only for very narrow distributions (\( m \geq 3 \)), and even this only if \( \Delta h/h_M \) is close to 1. Usually, \( \Delta h/h_M = 0.2 \) is not exceeded even by modern sedimentation devices. In this case the error can be neglected as a rule. The same is valid for pipette analysis, where a sink flow occurs at the pipette tip.\(^{(11-12)}\)

Further, it is assumed that the solid is a uniform system so that two particles differ only in size and no other property is relevant for measurement. This is not always so in practice. Frequently, the system consists of two or more components which may differ in some of the following properties affecting the sedimentation analysis:

1. particle size distribution \( Q(x) \)
2. particle shape distribution \( Q(\xi) \)
3. density \( \rho \) of the solid
4. refractive index \( m \) of the solid
5. mass attenuation coefficient \( \mu \) of the solid.

Bernhardt\(^{(116)}\) has investigated the problems resulting for incremental suspension methods. He found that a distinction must be made between properties affecting the sedimentation velocity and thus the particle sizes present on measurement level (2 and 3) and properties affecting quantity measurement (4 and 5).

The difference between components with respect to particle size distribution is insignificant and they do not produce incorrect measurements. In practice, however, components normally differ in all three properties 1 to 3.

For two-component systems in which the components with mass fractions \( \rho_1 \) and \( \rho_2 \) differ only in size distribution \( Q_{1,2}(x) \) and solid density \( \rho_1 \) and \( \rho_2 \), Equation (80) holds

---

**Figure 17** Influence of the measuring gap width on the measured results. (Reproduced from Bernhardt\(^{(11)}\), Copyright 1994, with kind permission from Kluwer Academic Publishers.)
where \(Q_3\) is the particle size distribution, \(Q_{3, \text{mea}}(x)\) is the measured (apparent) particle size distribution, \(Q_{3, \text{act}}(x)\) is actual particle size distribution and, Equation (81)

\[
f_1 = \frac{\rho_1 \rho_2 - \rho_m (\rho_1 p_2 + \rho_2 p_1)}{(\rho_1 - \rho_m)(\rho_1 p_2 + \rho_2 p_1)}^{1/2}
\]

\[
f_2 = \frac{\rho_1 \rho_2 - \rho_m (\rho_1 p_2 + \rho_2 p_1)}{(\rho_2 - \rho_m)(\rho_1 p_2 + \rho_2 p_1)}^{1/2}
\]

In rough approximation, Equation (82)

\[
\Delta Q_3 \approx p_1 (f_1 - 1) x_M [q_{3,1}(x_M) - q_{3,2}(x_M)]
\]

where \(q_{3,1}(x_M), q_{3,2}(x_M)\) are the frequency distributions of the two components at \(x_M\).

An analysis of this relationship shows: (116)

- Because the product \(p_1 (f_1 - 1)\) assumes an extreme value in the vicinity of \(p_2 = 0.5\), large errors in \(Q_3\) have to be expected here; the extreme value itself is determined by the density difference of the components.
- The error in \(Q_3\) furthermore depends on the particle size \(x\) and the difference of the frequency distributions of the two components at this position.

It is mostly the latter factor which makes the error relatively small even for large density differences. The examples of mixtures of \(\text{SiO}_2\) (\(\rho_1 = 2.65 \text{ g cm}^{-3}\)) and \(\text{Fe}_2\text{O}_3\) (\(\rho_2 = 5.55 \text{ g cm}^{-2}\)) calculated by Bernhardt (116) have errors \(\Delta Q_3 < 3\%\).

4.2.1.2 Gravimetric Pipette Methods In pipette analysis, the solids concentration at the measurement level (depth \(h\)) is determined by taking a sample of volume \(V\) (after time \(t\)) and subsequently determining the solid mass \(m\) by weighing (after drying). Then, Equation (83)

\[
Q_3(x) = \frac{c(h, t)}{c_0} = \frac{m(t)}{m_0} \frac{V_0}{V(t)}
\]

Pipette methods can be subdivided into the following groups:

- methods introducing the pipette from the top
  - pipette with fixed immersion depth
  - pipette with variable immersion depth
- methods with the pipette introduced from below
- methods with lateral introduction of the pipette.

Figure 18 shows some examples of the methods involving introducing the pipette from the top. Figure 18(a) reflects the arrangement proposed by Robinson (109) as early as 1922 in which normal laboratory devices are used as sedimentation vessel (1) and pipette (2). After each sampling, the pipette had to be removed from the suspension and then had to be reintroduced. This disadvantage was overcome by a development by Andreasen (113) whose improved version (11–12) is represented in Figure 18(b). Between pipette tip (2) and sample vessel (3) a special two-way stopcock (4) is installed allowing the transfer of the sample volume (10 cm\(^3\)) to an evaporating and
Sedimentation systems with a lateral pipette are mentioned here only for completeness sake; the systems developed by Esenwein, Berg and Stairmand [cited in Bernhardt\(^{113}\) and Berg\(^{53}\)] were only of limited or local importance.

4.2.1.3 Methods of Density Measurement

The fundamental equation for the application of density measurement for incremental sedimentation analyses is given by Equation (84)

\[
Q_3(x) = \frac{\psi(h, t) - \rho_m}{\psi_0 - \rho_m} \tag{84}
\]

where the suspension density \(\psi = cV(\rho_s - \rho_m)\).

Areometer Method. Bouyoucos\(^{114}\) was the first to report on the measurement of the suspension density \(\psi(h, t)\) by means of areometers. It was a fast method much used particularly for soil analysis between 1930 and 1960.\(^{74,120-122}\)

Measurement is performed in such a way that a suitable areometer is introduced into the suspension at certain intervals, and the density is read dependent on time. According to Rumpf\(^{70}\) the method is cumulative in the strict sense; however, there are fundamental obstacles to an evaluation in this sense. This is why since Casagrande\(^{123}\) the approach has been simplified by the concept of the areometer indicating the mean density at the depth of the center of the areometer head.

The method has grave disadvantages [see Rumpf,\(^{70}\) Conley\(^{124}\) and Allen\(^{116}\)].

Diver Method. To overcome certain disadvantages of the areometer method, Berg\(^{115}\) used miniature areometers without a shaft (divers) of accurately staggered density that remained in the sedimentation vessel during analysis. Such a body is always in the concentration range equivalent to its density. The measurement requires a certain number of divers with carefully adjusted density values. The depth of the diver is usually determined by means of a magnet drawing the divers to the glass wall of the sedimentation vessel. There are also some other designs.\(^{116,122}\)

4.2.1.4 Photoelectric Methods

Fundamentals. The photoelectric methods make use of the fact that a light beam of intensity \(I_E\) is attenuated to intensity \(I_A\) when crossing a suspension. The attenuation law (Lambert–Beer law after its discoverers) is, Equation (85)

\[
\ln T = \ln \left(\frac{I_A}{I_E}\right) = -A_V c_V L \tag{85}
\]
The theory of Mie\footnote{Bernhardt\textsuperscript{113}. Copyright 1994, with kind permission from Kluwer Academic Publishers.)}

where \( K(x) \) is the extinction function. If the transilluminated suspension contains a polydisperse solid of frequency distribution \( q_3(x) \), the corresponding use of Equation (86) leads to Equation (87):\footnote{Reproduced from Bernhardt,\textsuperscript{113} and Telle.\textsuperscript{113}}

\[
Q_3(x) = 1 - \frac{\ln T(t)}{\ln T(\infty)} \frac{K(x)}{K_0(x)} \frac{\ln T(\infty)}{\ln T(0)} \frac{\ln T(0)}{\ln T(t)} 
\]

where \( T = I/I_\infty (I_\infty = I_\lambda) \) at time \( t = \infty \) (solid-free). The difficulty in applying this relationship to sedimentation analysis has mainly to do with the extinction function \( K(x) \); it depends on a total of four quantities:

- particle size \( x \)
- wavelength \( \lambda \) of the light used
- the optical constants of solid and liquid
- the aperture angle \( \Theta \) of the optical system used.

There are three possibilities with respect to the extinction function:

- calculation from material data
- assumption of constancy
- experimental determination.

Calculation can in principle be done on the basis of the theory of Mie\textsuperscript{125} (see also van de Hulst\textsuperscript{126} and Kerker\textsuperscript{127}). Its use requires knowledge of the optical properties (ratio of refractive indexes) of solid and liquid, their absorption capacity (imaginary refraction index) and, furthermore, the well-founded assumption that the solid particles can be characterized by a spherical shape. Tables of refraction indexes and approximations of the extinction function are given in the literature (see Alex et al.,\textsuperscript{11–12} Bernhardt\textsuperscript{113}).

Theoretically, the extinction function must have the trend described in the following (see Figure 19). In the case of small aperture angles the function starts close to zero for large particles (\( \alpha = \pi x/\lambda > 100 \)). With decreasing particle size, its value grows to a maximum under strong oscillations and then rapidly decreases and turns into the curve of the Raleigh theory in the range \( \alpha < 1 \).

Practical cases often are far from these ideal conditions. Frequently, there is neither a spherical shape nor a homogeneous solid whose optical properties are known. Examples include most rocks, ores, coal, silicatic raw materials, and so on.

The influence of the aperture angle \( \theta \) on the extinction function has been studied by Weichert\textsuperscript{128}. Some of his results are represented in Figure 19.

It is evident that:

- The aperture angle \( \theta \) controls the position of the final value to which the extinction function tends for large particles;
- for a large aperture angle \( \theta \), the assumption of a constant value of the extinction function for a wide range of fineness is more justified than for small \( \theta \).

The latter fact led Allen\textsuperscript{129} to improve the wide angle photosedimentometer according to Harner and Musgrave\textsuperscript{130} and Telle.\textsuperscript{113} For \( K(x) = \text{constant} \), Equation (88) is obtained from Equation (87)

\[
Q_3(x) = \frac{\ln T(\infty)}{\ln T(0)} \frac{\ln T(t)}{\ln T(\infty)} \frac{\ln T(\infty)}{\ln T(0)} \frac{\ln T(0)}{\ln T(t)} 
\]

If the direct determination of the volume distribution \( Q_3(x) \) is replaced by the surface distribution \( Q_2(x) \), the very simple and well known relationship, Equation (89), is obtained:

\[
Q_2(x) = \frac{\ln I(\infty)/I(t)}{\ln I(\infty)/I(0)} = \frac{\ln I(\infty)/I(t)}{\ln I(\infty)/I(0)} 
\]

where \( I_0 \) is \( I_\lambda \) at time \( t = 0 \); \( I_\infty \) is \( I_\lambda \) at time \( t = \infty \) (solid-free); \( I_t \) is \( I_\lambda \) at time \( t \).
When using this approach it must be taken into account that while it is possible to measure up to the given range, strictly speaking there must not be any solid fractions below the smallest size indicated; the greater the actual fines fraction, the higher the error of measurement.

The problems mentioned describe the whole approach as unsatisfactory. Therefore, there have been attempts to determine experimentally the extinction functions for given materials and devices since the introduction of this sedimentation method. While these essentially relate to measurements of narrowly classified or monodisperse materials, Johne and Ramanujam describe a method based on the studies of Locher for which the frequency distribution \( q(x) \) of a calibration material has to be known.

Weichert solved the problem by measuring the transmission of a sedimenting system dependent not only on the time \( t \) (or size \( x \)) but also the wavelength \( \lambda \). He was able to show that even simultaneous measurement at three different wavelengths would be sufficient if the dependence of the refractive index on the wavelength could be neglected for the selected conditions. This method has the advantage that the simple procedure of modifying the photometric sedimentation analysis simultaneously provides the information required for the calculation of the size distribution, with the material and device dependent influences being taken into account.

**Photosedimentometer.** Photosedimentometers are subdivided into wide angle and small angle systems. Figure 20 gives a comparison of the two principles.

In the small angle photometer (aperture angle \( \Theta \leq 3^\circ \)), the light emitted by a lamp (1) is formed into a parallel bundle by a lens system (2); a part is transmitted to the suspension in a measurement cuvet (4) through a diaphragm (3). By means of diaphragm (5), the arriving radiation is transmitted to the detector (6) under a small aperture angle.

In contrast, no parallel light is used in the wide angle configuration; lamp (1), lens system (2) and diaphragm (3) are designed so that the suspension is transilluminated by a light bundle of the type shown. Since there is no diaphragm between cuvet (4) and detector (5), the aperture angle is very wide (\( \Theta > 40^\circ \)).

The two systems have occasionally been the subject of comparative analysis; neither was revealed to be superior with respect to the other. This is why both systems are still in use.

Turbidity measurements for the characterization of colloid–chemical processes and conditions have been known for a long time (e.g. see von Hahn). First studies on the use of this principle in sedimentation analysis for the determination of particle size distributions were done by Skinner and Boas-Traube and later by Rosé and Telle. The latter developed a small-angle device which became known by the name of the manufacturer, Evans Electroselenium Ltd., London (EEL sedimentometer).

The simultaneous development of the wide angle technique can be traced back to investigations by Harner and Musgrave and Telle, the device described by the latter was built by Leitz, Wetzlar. Allen used the wide angle principle, initially without height adjustment. Later he reported a new development that allowed the sedimentation vessel to be lower and then one that allowed the optical system to shift upwards. The latter is known under the name of Ladal wide angle scanning photosedimentometer (WASP). A similar version, however, with downward shifting of the sedimentation vessel is distributed by Microsal, London, under the name Computerised WASP.

The Fritsch company, Idar-Oberstein, manufactures a wide angle device under the designation Scanning Fotosedimentograf (Analysette 20) in which the sedimentation vessel is fixed and the optical system is moved upwards at a constant velocity.

The small angle device Sedigraph 5500 L of Micrometrics, Norcross provides for the lowering of the measurement cuvet, albeit not at a constant velocity but following a scanning program in which the velocity diminishes with increasing sedimentation time. As a result of measurement, a surface distribution according to Equation (89) is recorded.

The spectral photosedimentometer described by Weichert uses light of three different wavelengths. Both the sedimentation vessel and the small angle...
optical system are at rest during measurement; however, the latter is a multiple system distributed along the sedimentation path.

A multiple optical system distributed along the sedimentation path is also used in the device called Lumosed which was developed by Staudinger et al.\textsuperscript{137} A commercially available device from Retsch uses white light at three different sedimentation heights; a special procedure was developed for the combination of the results, which are evaluated under the assumption of a constant extinction function. At the same time, a number of values of the extinction function can be calculated by means of a calibration measurement with a substance of known distribution; these values can then be used in all measurements of the same material system.

In conclusion, another group of devices shall be mentioned which can be used in both gravitational and centrifugal fields. These are products of several important Japanese firms (Shimadzu Corp., Tokyo, Horiba, Kyoto, Seishin Enterprise Ltd., Tokyo); their main use, however, is as centrifuges. Therefore, they will be dealt with in section 4.3.

4.2.1.5 Methods Based on Gamma Attenuation

Fundamentals. Gamma radiation or X-rays of intensity $I_E$ impinge on a suspension of thickness $L$, the intensity $I_A$ after transillumination is calculated on the basis of the Lambert–Beer law, Equation (90):

$$\ln \frac{I_E}{I_A} = \mu_{m,\text{eff}} \rho_{c,\text{eff}} L.$$  

For a homogeneous solid in a liquid the very simple Equation (91) holds:

$$Q_3(x) = \frac{c_Y(t)}{c_0} = \frac{\ln(I_{\infty}/I_0)}{\ln(I_{\infty}/I_0)}$$  

For two solids (with different particle size distributions, different densities and mass attenuation coefficients) the measured distribution is produced by a more complicated relationship which was developed by Bernhardt.\textsuperscript{116} He found that the differences between the measured and the true particle size distributions are only considerable for large mass portions near the maximum of the frequency distribution. The theory was confirmed experimentally for the measurement of mixtures of SiO$_2$ and Fe$_2$O$_3$ by using a sedigraph 5000 D (see Figure 21).

In general, it can be said that the particle size distribution of the components essentially determines the shape of the error curve and the solid mass proportions essentially control the value of the errors. It is difficult to give a general assessment of the effects of the other parameters, density, attenuation coefficient and solids concentration.

Gamma-ray and X-ray Sedimentometer. The first to propose the use of X-rays for incremental sedimentation analysis were Brown et al.\textsuperscript{138} Their commercial system (ICI Stevenston, Scotland) is described in Allen.\textsuperscript{16} Later improvements used different X-ray sources\textsuperscript{139–142} and radionuclides.\textsuperscript{143,144} Rumpf et al.\textsuperscript{68} deal with the criteria of selection for different types and energies of sources as well as the required activity. Among more recent developments, two deserve to be mentioned: the LADAL X-ray sedimentometer\textsuperscript{16,144} has a fixed

![Figure 21](image-url)  

Figure 21 Total systematic error due to the density and attenuation coefficient of heterogeneous solids (SiO$_2$ + Fe$_2$O$_3$) ($\rho_1$ mass proportion of SiO$_2$): (a) calculated; (b) experimental (Sedigraph 5000 D). (Reproduced from Bernhardt,\textsuperscript{13} Copyright 1994, with kind permission from Kluwer Academic Publishers.)
measurement cell. After a certain time, which can be
selected within defined limits, the radiation source and
the proportional counter are moved upwards in the
direction of the liquid surface at a constant velocity
(approx. 1.5 cm min\(^{-1}\)). Maximum sedimentation height
is 18 cm, the minimum value is 1 cm. The recommended
range determined by these geometrical conditions is
between 2 and 100 \(\mu\)m. The necessary solids concentration
is \(c_V \leq 1\%\) for materials with an atomic number \(\geq 12\).

Sedigraph 5000 D, 5000 ET or 5100\(^{(140,145)}\) have a
measurement cell moving downwards at a reducing
velocity between the radiator (air-cooled X-ray tube with
tungsten spot) and the scintillation counter. A scheme
for the computer controlled Sedigraph 5100 is given in
Figure 22.

A well-dispersed suspension is introduced into a sample
chamber from which it circulates through the analysis cell
by means of a peristaltic pump. At the start point of
the analysis the pump stops and the particles begin to
settle in the analysis cell. The measurement of the X-ray
attenuation begins near the cell bottom, and because of
the shift down the cell the distances between the particles
become smaller and smaller. In this way acceptable
analysis times are obtained even for very small particle
sizes under 1 \(\mu\)m. After the analysis the suspension is
pumped to a waste reservoir and using a second peristaltic
pump, fresh rinse liquid flows through the system.

The Sedigraph device family has established itself well
since its invention.\(^{(146-150)}\)

4.2.1.6 Repeated Decanting

The method of repeated
decanting goes back to the elutriation analyses that
were usual in soil analysis until some time ago (see
older standard works\(^{(103,105,151)}\)). This technique is related
to names such as Appiani, Atterberg, Kühn, Wagner,
Wahnschaffe, and so on; the principle is shown in
Figure 23.

Even though this method is probably not used nowa-
days for sedimentation analysis, it is a simple method
for preparative production of particle fractions below the
sieving limit. This is why it will be briefly considered here.

If the suspension which was homogeneous at time \(t = 0\)
is allowed to sediment in a vessel (see Figure 23), the
particle mass \(m_a\) in the bottom space after time \(t\) is given
by Equation (92)

\[
\frac{m_a}{M} = 1 - \left( \frac{h_1}{h_2} \right)^x 1 - \int_0^2 q_3(x) \, dx \quad (92)
\]

Now in decanting, the volume of the suspension above
the bottom space is removed after a given time \(t\) and then
replaced by solid-free liquid up to level \(h_2\). After mixing,
the supernatant suspension is again removed after time \(t\)
and so forth, until the amount of solids \(m_s/M = 1 - m_a/M\)
tends to zero and \(m_s/M = 1 - Q_3(x)\) can be assumed
with sufficient accuracy. This, of course, is why repeated
decanting can be looked upon as an incremental method.

Rumpf and Alex\(^{(152)}\) analyzed the process of decanting
by calculating the grade efficiency curve after \(n\) times.
Decanting has to be repeated very often to obtain a
high cut sharpness, that is, it requires much time. For
instance, at least 32 decanting steps are required for a proportion \(<0.1\%\) for \(x = 0.9\ x_j\), but even then approx. 5\% of the particles with 0.95 \(x_j\) that were in the feed are still present in the bottom space. An interesting result is that a drastic reduction in the bottom space (\(h_1/h_2\) near 1) does not give any improvement. Suggestions for the suitable design of decanting vessels are given in the literature.\(^{16,103,105,151–153}\)

4.2.2 Cumulative Suspension Methods

4.2.2.1 Fundamentals

There are two types of cumulative suspension methods:

- methods based on the measurement of \(m_a\) (the amount of solids that have sedimented from the suspension volume)
- methods based on the measurement of \(m_s\) (the amount of solids still in the suspension volume).

Consequently, there are two different basic relationships for the determination of the particle size distribution. Equations (93) and (94)

\[
1 - Q_3(x_i) = \frac{1}{M} \left( m_a - t \frac{dm_a}{dr} \right) = \frac{1}{M} \left( m_a - \frac{dm_a}{d \ln t} \right) \quad (93)
\]

\[
Q_3(x_i) = \frac{1}{M} \left( m_s - t \frac{dm_s}{dr} \right) \quad (94)
\]

where \(M\) is the total solid mass in the suspension.

Equations (93) and (94) provide the basis of all cumulative principles. Their derivation originated with Odén\(^{106}\) but is also found in later works, sometimes in a modified form.\(^{103,154,155}\)

4.2.2.2 Measurement of Sedimented Amount in Solids

All known versions of sediment measurement differing only in the physical measuring principle are shown in Figure 24.

Sedimentation Balance. The principle of the sedimentation balance (Figure 24a) was technically realized by Odén as early as 1915/1916\(^{106}\) and in 1920 was available as an automatic device which registered the sedimented mass \(m_s\) dependent on time (see Gefner\(^{103}\)). Since then, there have been many successors that have maintained the basic principle, only adapting the device to the state of the art.\(^{130,154,156–162}\)

The way the balance pan is arranged has an impact on the measurement range. An arrangement like that schematically represented in Figure 24(a) leads to density convection flows at the pan brim\(^{1–12,69}\) so that parts of the solids < 3–4 \(\mu m\) are transported under the pan and are thus lost for the measurement. The effect is avoided by a design according to Alex et al.\(^{1–12}\) and Bürkholz.\(^{163}\)

In view of their automatic mode of operation and their low solids concentration (<0.1 vol\%), sedimentation balances were widely used in the past. This is demonstrated by the multitude of commercial designs (e.g. Gallenkamp (England), Cahn (USA), Mettler (Switzerland), Sartorius (Germany), Shimadzu (Japan)).\(^{164}\) Because of their relatively long analysis time, nowadays these balances are used only where the advantages outweigh this disadvantage or where other systems cannot be used (e.g. Kowalski\(^{165}\)).

For the older designs, the measured curve \(m_a(t)\) was evaluated graphically according to Equation (93) followed by further improvements (see in von Hahn\(^{105}\)).

Sedimentation Column. Particularly among English publications, there is information concerning the use of so-called sedimentation columns whose basic principle is traced back to Stairmand;\(^{166}\) similar designs were already mentioned by Gefner\(^{103}\) and von Hahn.\(^{105}\) The principle is represented in Figure 24(b). The solid mass sedimented from a very thin suspension (\(c_V < 0.1\%)\) is released from the vessel at staggered time intervals, and the sample volume (10 cm\(^3\)) is automatically replaced by solid-free liquid from a second vessel. There are even more simple solutions (see Allen\(^{16}\)) which do not include a liquid reservoir. Evaluation is done either by using Equation (93) or an approximation method proposed by Stairmand.\(^{166}\)

Beta Backscattering. The principle represented in Figure 24(c) is based upon beta radiation being directed towards the solids sedimented on the bottom of the suspension vessel and the subsequent measurement of the backscattered radiation intensity. According to Hardwick and Laundy\(^{167}\) the backscattered intensity depends only
on the so-called effective atomic number \( z_{\text{eff}} \) of the investigated material.

As an example: for water, \( z_{\text{eff}} \) is approximately 7, for ZrO\(_2\) it is approximately 32. This difference produces the measurement effect. By the solid sedimenting to the bottom, water is displaced so that \( z_{\text{eff}} \) and thus the backscattered intensity change with the solid mass within a certain range of layer thickness.

An alternative device using \( \beta \)-radiation is the transmission scheme developed by Curzio.\(^{(168)} \) Here, the radiation source is fastened above the bottom in such a way that the radiation is attenuated by the solid on the bottom dependent on the layer thickness before it reaches the detector.

### 4.2.2.3 Measurement of Amount of Solids in Suspension

The principles based on this method are represented in Figure 25.

The manometer method (Figure 25a) goes back to works by Wiegner,\(^{(107)} \) Geßner\(^{(103)} \) and von Hahn,\(^{(105)} \) Lange and Gass\(^{(169)} \) used a highly sensitive pressure measurement device which allowed a drastic reduction of the sedimentation height. This method was later been automated.\(^{(170)} \) The particle size distribution is calculated from the measured pressure curve \( \Delta P(t) \) by Equation (95)

\[
Q_3(x) = \frac{\Delta P(t)}{\Delta P_0} - \frac{t}{\Delta P_0} \frac{d\Delta P}{dt}
\]

In the case of cumulative diving methods, a distinction has to be made between those with constant and those with variable immersion depth (see Figure 25b and c). The use of these methods is simplest if the areometers have a constant cross-section over their entire length; other shapes, however, are possible as well.\(^{(103,105,153,171)} \)

The diving balance (Figure 25b) allows the weight force \( P(t) \) of the diving body to be determined dependent on the time \( t \) and the particle size distribution to be calculated from Equation (96)

\[
Q_3(x) = \Pi - t \frac{d\Pi}{dt}
\]

where

\[
\Pi = \frac{P(t) - P_\infty}{P_0 - P_\infty}
\]

where \( P_0 = P \) for \( t = 0 \), \( P_\infty = P \) for solid-free liquid.

The swimming balance (Figure 25c) indicates the variable immersion depth \( h(t) \); if \( h_0 \) (at \( t = 0 \)) and \( h_\infty \) (solid-free liquid) are known as well, the particle size distribution is calculated according to Equation (98):\(^{153,171} \)

\[
Q_3(x) = \frac{h_0}{h(t) - h_0} \frac{h_\infty - h(t) + t(dh/dt)}{h(t) - t(dh/dt)}
\]

Single decanting (Figure 25d) as a cumulative method was investigated by Bennert\(^{(172)} \) and Schultz\(^{(173)} \); the experimental side of decanting is described in the literature.\(^{(16,103,105,151–153,172)} \) Measuring the mass \( m_s \) above the bottom space in several vessels at different times \( t \) or even in one vessel with different \( h_1 \) and \( t \) valves, the particle size distribution is determined by the modified Equation (94), Equation (99)

\[
Q_3(x) = \frac{h_2}{h_1} \frac{1}{M} \left( m_s - t \frac{dm_s}{dt} \right)
\]

### 4.2.3 Line Start Methods

If a thin suspension layer of thickness \( \Delta h \ll h \) is arranged on top of a solid-free liquid column and disturbance-free sedimentation is secured, we will immediately obtain in depth \( h \):

- for incremental measurement: the frequency distribution \( q_3(x) \),
- for cumulative measurement: the distribution \( Q_3(x) \).

The fact that this is a very attractive possibility was the reason that the range of application of this method was constantly investigated or attempts were made to expand it by the development of new devices; this, however, proved possible only to a certain limit. The main reason for this is the difficulty of ensuring disturbance-free sedimentation. Mainly at the beginning, instability occurs caused by the difference in density between the suspension and the solid-free liquid. The

---

**Figure 25** Cumulative suspension methods; measurement of solid mass in suspension. (a) Manometer method, (b) diving balance, (c) swimming balance, (d) single decanting. (Reproduced from Bernhardt,\(^{(13)} \) Copyright 1994, with kind permission from Kluwer Academic Publishers.)
consequence is streak-type vortexing leading to solid particles entering the liquid with high speed. The only reliable method of solving this problem is the density gradient method known from centrifugal equipment (see Allen et al.\textsuperscript{(1–12)}). In gravity sedimentation, however, elimination of this effect has been tried by reduction of the solids concentration\textsuperscript{(174)} or extreme expansion of the sedimentation path.\textsuperscript{(146)}

The quantity measurement is exclusively cumulative and usually restricted to manometric measurement or gravimetric measurement in the form of a sedimentation balance.\textsuperscript{(146,174)} A further device, the so-called US sedimentometer\textsuperscript{(149)} uses the sediment volume as a measured variable; its preferential use in the manufacture of abrasives, however, obviously is due to the fact that the line start method offers a good possibility of determining even very tiny fractions of large grains, which is decisive in this area.

A device proposed by Muschelknautz\textsuperscript{(175)} deserves to be mentioned; it imitates cumulative layer formation by weighing in two sedimentation vessels of different height. This removes all the above problems.

The use of air as a sedimentation medium offers the possibility of shifting the lower application limit to a few micrometers while maintaining long sedimentation paths.\textsuperscript{(176)} This method was used by several authors.\textsuperscript{(177–179)} The Micromerograph\textsuperscript{(177)} uses a sensitive torsion balance for quantity measurement. The solid is fed by pressurized air; the accompanying dispersion effect is assumed to be sufficient for most cases.\textsuperscript{(180,181)} A device described by Kouzov\textsuperscript{(178)} uses a conventional air gun; at the same time, this is one of the rare cases of an incremental quantity measurement (photometric evaluation of plates exposed for different periods of time which are installed at the bottom of the sedimentation vessel).

Another application of the line start method is the determination of the drop size of sprays using a sedimentation balance.\textsuperscript{(179)}

### 4.3 Methods Used in the Centrifugal Field

#### 4.3.1 Fundamentals

**4.3.1.1 Modified Stokes Law** In order to overcome the disadvantages of gravity sedimentation in the range of small particles < 1 μm (e.g. diffusion, long measurement periods), a centrifugal field can be used instead. However, the acceleration $b$ is a function of radius $r$ ($b = w^2 r$) so that Stokes velocity becomes, Equation (100)

$$\frac{dr}{dt} = \frac{\Delta \rho}{18 \eta} w^2 r x^2 \quad (100)$$

For constant angular velocity $w$, an integration for any sedimentation between an inner radius $r_i$ and an outer radius $r_a$ yields, Equation (101)

$$\ln \frac{r_a}{r_i} = \frac{\Delta \rho}{18 \eta} w^2 x^2 t \quad (101)$$

In practice, acceleration and deceleration phases will always occur in addition to phases of constant angular velocity; therefore, the curve of $w(t)$ has to be taken into account in the integration, Equation (102):

$$\ln \frac{r_a}{r_i} = \frac{\Delta \rho}{18 \eta} w^2 \int_0^{t_{\text{max}}} x^2 \, w^2(t) \, dt \quad (102)$$

To be able to calculate the particle size $x$ for a given running time $t_{\text{max}}$ on this basis, $w^2(t)$ can be plotted against $t$, and the area under the curve can be determined. Rumpf et al.\textsuperscript{(188)} propose the use of an effective time $t_{\text{eff}}$ for the case of a constant acceleration and deceleration, Equation (103):

$$t_{\text{eff}} = \frac{t_1}{3} + (t_2 - t_1) + \frac{t_3 - t_2}{3} \quad (103)$$

where $t_1$ is the end of acceleration phase, $t_2$ is the start of deceleration phase, and $t_3$ is the end of deceleration phase.

The incremental and cumulative principles used for quantity measurement in centrifuges are nearly the same as in the gravitational field. In the following, the theoretical basis will be briefly described (see also several overviews\textsuperscript{(13,16,53,182–184)})

#### 4.3.1.2 Quantity Measurement for Suspension Methods; Incremental Principle

The suspension level in the centrifuge vessel reaches radius $r_a$. There is an incremental measurement device at $r$ for determining the solids volume concentration $c(r, t)$. The bottom of the suspension vessel is at radius $r_a$. Then the integral Equation (104) holds

$$\frac{c(r, t)}{c_0} = \exp \left\{ -2 \frac{\Delta \rho}{18 \eta} w^2 x^2 t \right\} q_3(x) \, dx \quad (104)$$

and for a constant angular velocity, Equation (105)

$$\frac{c(r, t)}{c_0} = \exp \left\{ \frac{x}{x_t} \ln \frac{r_i}{r} \right\} q_3(x) \, dx \quad (105)$$

Equations (104) and (105) are fundamental equations for incremental suspension methods in the centrifugal field. Their use in the evaluation of measured values depends on the experimental approach. The following procedures are possible:

1. The dependence of the solids concentration on time $t$ is determined at distance $r$. In this case, there is no general solution to Equation (104) for the particle...
size distribution that is being sought, so there are various approximations. The simplest and most common was proposed by Norton and Speil\textsuperscript{[185]} assuming that \( r/r_1 \) tends to 1, which is true only for centrifuges with big rotors and short sedimentation paths (long-arm approximation). Evaluation is done as in the gravity field but taking into account the increased acceleration. The error of this approximation in comparison with an exact evaluation was investigated by Alex.\textsuperscript{[186]}

There is also the theory developed by Kamack\textsuperscript{[187]} which reaches an approximate solution by assuming that the dependence of the solids concentration is linear between two measurement points \( t_1 \) and \( t_2 \). Then, Equation (106) can be written:

\[
\frac{c(x, t')}{c_0} = \sum_{k=1}^{a_i} q_3(x_{i,t}) B_{k,i} \exp \left( \frac{x}{x_{i,k}} \ln \frac{r_1}{r} \right) \, dx \tag{106}
\]

obtaining a linear set of equations for the discrete values of \( q_3(x_{i,t}) \).

2. The solids concentration is measured dependent on the radius \( r \) at a fixed time \( t \). Equation (105) then can be differentiated with respect to \( x \), and we obtain Equation (107):\textsuperscript{[53,68]}

\[
Q_3(x_i) = \frac{c(r)/c_0}{r_1^2} \frac{d}{dx} \frac{c(r)}{c_0} \tag{107}
\]

Hence, if \( c(r)/c_0 \) is plotted against \( (r/r_1)^2 \), the distribution is determined by integration.

3. Svarovsky and Svarovsk\textsuperscript{a}\textsuperscript{[188]} use a solution of Equation (104) which was also proposed by Kamack, obtained for the distribution after time \( t \) (when the particle size \( x \) passes the measurement level). Their equation is an exact solution but the contained convolution integral can be solved only numerically. Therefore, Svarovsky and Svarovsk\textsuperscript{a}\textsuperscript{[188]} replaced it by an analytical approximation easily produced by an analogous calculation scheme, enabling the continuous evaluation of the sedimentation curve. A further solution was suggested by Fautz.\textsuperscript{[184]}

4. Finally, the fundamental equations can also be solved by using analytical distribution functions for \( q_3(x) \) and determining their parameters.\textsuperscript{[188]}

4.3.1.3 Quantity Measurement for Suspension Methods; Cumulative Principle

The mass \( m_s/M \) which is in the bottom space \( r_{a2} - r_{a1} \) after time \( t \) is given by

\[
\frac{m_s}{M} = 1 - \frac{\kappa}{r_{a1}} \int_0^{r_{a1}} \frac{r^2}{r_{a1}^2} \frac{q_3(x)}{dQ_3} \tag{108}
\]

If the cumulative measurement is organized so that the mass that sedimented at the bottom is determined (sedimentation balance), that is \( r_{a1} = r_{a2} = r_s \), Equation (108) is simplified to Equation (109)

\[
\frac{m_s}{M} = 1 - Q_3(x_i) + \frac{1}{1 - (r_i/r_s)^2} \int_0^{r_s} \frac{r}{r_i} \ln \left( \frac{r_i}{r_s} \right) q_3(x) \, dx \tag{109}
\]

This is the relationship which was indicated by Romwalter and Vendl.\textsuperscript{[189]} For the case where \( m_s/M \) is measured dependent on time there is a well-known solution originally proposed by Robinson and Martin\textsuperscript{[190]} [cited by Sullivan and Jacobsen\textsuperscript{[185]}]. An approximation method was suggested by Lloyd et al.\textsuperscript{[191]}

As with the incremental methods, there are exact solutions for the case where measurement is dependent on the radius at a constant time. The first possibility is to measure the sedimented mass \( m_s/M \) dependent on the inner radius \( r_i \). According to Brown\textsuperscript{[192]} the solution is, Equation (110)

\[
1 - Q_3(x_i) = \mu(x_i) - \frac{r_i^2 - r_1^2}{2r_1} \frac{d\mu}{dx} \tag{110}
\]

where \( \mu = m_s/M \).

A second possibility is to vary the outer radius \( r_s \) according to a proposal made by Donoghue and Bostock\textsuperscript{[193]} so that, Equation (111)

\[
1 - Q_3(x_i) = \mu(x_s) + r_s^2 - r_1^2 \frac{d\mu}{dx} \tag{111}
\]

If the solid mass in suspension \( m_s \) is responsible for the measured effect, Equation (112) holds:

\[
\frac{m_s}{M} = \frac{\kappa}{r_{a1}} \int_0^{r_{a1}} \frac{r^2}{r_{a1}^2} \frac{q_3(x)}{dQ_3} \tag{112}
\]

For repeated decanting until the solid mass \( m_s/M \) in the supernatant liquid tends to zero (this is absolutely usual for preparation purposes) \( m_s/M = 1 - Q_3(x_i) \) for the solid mass in the bottom space. Rumpf and Alex\textsuperscript{[152]} have again developed the grade efficiency function dependent on the number of decanting steps to approximate this state; see examples in Bernhardt.\textsuperscript{[13]}

In single decanting, the solid mass \( m_s/M \) in the volume above the bottom space is usually determined. To obtain the distribution \( Q_3(x_i) \), Weichert\textsuperscript{[194]} has proposed a
similar method to that of incremental analysis: single decanting operations are carried out at different times and \( m_s/M \) is determined dependent on time \( t \). Linearity is assumed between the measurement points so that we can write Equations (113) and (114):

\[
\frac{m_S(x_{i,k})}{M} = \sum_{l=1}^{k} q_3(x_{i,l}) A_{k,l} \tag{113}
\]

\[
A_{k,l} = \int_{0}^{x_{i}} \exp \left\{ \left( \frac{x}{x_{i}} \right)^2 \ln \left( \frac{r_1}{r_{a1}} \right)^2 - \frac{r_1^2}{r_{a1}^2} \right\} q_3(x) \, dx \tag{114}
\]

For \( q_3(x_{i,l}) \), a linear set of equations is again obtained by analogy with Kamack’s theory.\(^{(187)}\)

4.3.1.4 Quantity Measurement for Line Start Methods

The mathematical difficulties of the suspension methods have repeatedly led to the use of line start methods in sedimentation centrifuges. As in the gravity method, a thin suspension layer has to be brought to the top of a solid-free liquid. Then, the frequency distribution \( q_3(x) \) (incremental measurement) or the distribution \( Q_3(x) \) or \( 1 - Q_3(x) \) (cumulative measurement) is obtained directly (with restrictions for light optical incremental methods\(^{(16)}\)). The disadvantage of this simplification, however, is the considerable experimental difficulties caused by the formation of streak-type mixing phenomena at the interface between suspension and pure liquid which falsify the result. A detailed description and wide bibliography are given by several authors.\(^{(1–12,195,196)}\) Accordingly, the cause of this problem is mainly the instability of the superposed layers which leads to a special form of density convection flow. According to Alex et al.,\(^{(1–12)}\) two conditions have to be met to prevent such streak formation:

- The density of the superpositioned suspension has to be smaller than that of the pure sedimentation liquid. Both liquids have to be miscible to avoid additional problems caused by wetting.

- The solids concentration has to be small enough that the particles travelling from the suspension positioned on top of the pure sedimentation liquid cannot produce density convection flows by their presence. This is guaranteed for solids concentrations under 0.01 %, a range for which, however, none of the usual methods of quantity measurement works.

Therefore, the so-called density gradient method has to be used as the only existing way of avoiding streak formation; its successful application is described by Alex et al.,\(^{(1–12,197)}\) Brugger\(^{(197)}\) and Coll and Searles.\(^{(198)}\) Its content is to introduce into the centrifuge, in a suitable way, a sedimentation liquid whose density increases in the radial direction. This requires some experimental effort which will probably not be spent on routine analyses, since the problems of suspension methods can be solved by modern computer equipment.

In contrast, Kaye\(^{(199)}\) holds the opinion that the above difficulties in the line start methods in many cases are caused by the lack of stability of the centrifuge structures at high rotational speed.

4.3.2 Sedimentation Centrifuges

Since the first work by Svedberg and co-workers\(^{(52,108)}\) on the use of centrifuges for particle size analysis, there have been a large number of publications on methodological and technological solutions. An overview and historical development are given in the monographs by Allen,\(^{(16)}\) Chodakov and Judkin,\(^{(182)}\) Batel,\(^{(153)}\) Bernhardt,\(^{(13)}\) Köster,\(^{(151)}\) Geßner\(^{(103)}\) and von Hahn\(^{(105)}\) as well as by the Analytical Methods Committee.\(^{(14)}\)

On the whole, the experience seems to have been accepted according to how much methodological and technological effort is needed for accurate measurement. This applies both to the case of sedimentation in orbiting vessels (bucket centrifuges) and to the rotation of the suspension in a cylindrical vessel like a concentric ring (disk centrifuges).

4.3.2.1 Centrifuges with Incremental Measurement

The three main principles are shown in Figure 26.

---

Figure 26 Basic principles of sedimentation centrifuges with incremental quantity measurement: (a) pipette centrifuge, (b) photosedimentation centrifuge, (c) X-ray or γ-ray centrifuge. (Reproduced from Bernhardt,\(^{(13)}\) Copyright 1994, with kind permission from Kluwer Academic Publishers.)
**Pipette Centrifuge.** This device (Figure 26a) is usually a disk centrifuge. The suspension rotates like a ring in the disk rotor (1) into which four and eight pipettes stand and participate in the rotation. It has to be ensured that a tight connection is created between the rotating pipette shaft and the part of the sample which is at rest (stopcock (4), glass vessel (5)), for instance by device (3). When a vacuum is applied, the suspension sample flows into the sample vessel (5) from where it can be taken for further treatment (drying, weighing). The evaluation is done either in the gravity field (long-arm approximation), as for example in the centrifuges by Slater and Cohen\(^\text{200}\) or Gupta\(^\text{201}\) or by one of the approximations of Equation (105) as for example in the centrifuge according to Kamack\(^\text{187}\) or the modern Ladal pipette centrifuge\(^\text{202}\) and the Andreasen pipette centrifuge of Frithsch.

**Photosedimentation Centrifuge.** In the older types of centrifuge that use this principle, the centrifuge rotor (1) is a disk (see Figure 26b). Through the ring-shaped suspension, a light beam which is produced by the lamp (2) and optical device (3) (lens, prism) is emitted at a certain point and falls on the detector (4) on the opposite side. Light source and detector can also be shifted in the direction of the axis to shorten the measurement time (e.g. Allen and Khalili\(^\text{203}\)).

The first photosedimentation centrifuge was developed by Kaye and Jackson;\(^\text{204}\) it was followed by the version which became known as the Joyce–Loebl centrifuge.\(^\text{1–13}\) In both cases, a line start technique was used, with the usual problems in spite of special prescriptions (buffer layers etc.).\(^\text{195,196}\) Allen tried to circumvent the problems by developing a centrifuge with suspension technique (Ladal photo centrifuge\(^\text{203}\)) which involved the evaluation problems discussed by Lloyd et al.\(^\text{191}\) and Svarovsky and Svarovska.\(^\text{188}\)

Several modern Japanese sedimentation centrifuges have abandoned the disk rotor and use rotating measurement cells with a rectangular cross-section instead. Two of these cells are mounted on the rotor, one being filled with suspension and the other opposite being used for balancing or reference purposes. When the rotor is at rest, the devices can be employed as gravity photosedimentometers.

As discussed already, incremental photoelectric quantity measurement requires knowledge of the extinction function, and particularly so in the measurement range of the centrifuges (0.01–10 µm). In the centrifuge devices of Shimadzu and Horiba, a solution to this problem has been attempted by the possible use of a fixed standard extinction function or an extinction function obtained in a different way. This approach is not satisfactory either, since the effective extinction function of the investigated material is not known in many cases and the user does not know how great is its deviation from standard.

Weichert\(^\text{208}\) solved this problem by an experimental determination of the extinction function, however, the expense of the measurement and calculation is very high. This can be the reason for the fact that there has been no commercial use of the method.

**X-ray or γ-ray Centrifuges.** As is well known, the problem of the extinction coefficient does not exist for X-rays or γ-radiation. The principle represented in Figure 26(c) is completely analogous to the light optical method. The disk-shaped rotor (1) is subject to radiation from a suitable radiation source (2) at a certain point in the suspension ring; the intensity of the radiation incident on the opposite side is measured by the detector (3). Source (2) and detector (3) can be shifted in a radial direction to reduce the measurement time. The Ladal γ-ray centrifuge\(^\text{202,205}\) uses a radioactive isotope (Pm 147/Al) and a scintillation counter. To obtain a measurable attenuation effect, the solids concentration has to be considerably higher than with photoelectric methods. This may lead to restrictions on use since the stability of the suspension strongly depends on the solids concentration for very small particles.

The development of a disk centrifuge (Du Pont/Brockhaven Scanning X-ray Disc Centrifuge) is described by Allen.\(^\text{206}\) This device can be used both in the gravity field and the centrifugal field, that is, in a measurement range between 0.01 and 100 µm. Finely focussed X-rays are directed to the sedimentation path by a scanning program so that only a few minutes are required for the whole measurement.

4.3.2.2 Centrifuges with Cumulative Measurement

Some of the best known principles of cumulative sedimentation centrifuges are represented in Figure 27.

**Manometer Centrifuge.** In this scheme borrowed from gravity sedimentation (Figure 27a), on the centrifuge rotor (1) there is only one measurement cell (2) at which the pressure difference between upper and lower end is measured. The counterweight (4) ensures an equilibrium. By means of cables (3), the pressure is supplied from the rotating centrifuge shaft to the data transmitter (5) and then to the differential pressure converter (6) producing an electrical signal for further evaluation. The development of the device originated with Böwing and Gast;\(^\text{207}\) Lauer\(^\text{208}\) reported on further developments and the version marketed by Alpine. This centrifuge is designed so that the long-arm approximation and the related evaluation algorithm can be employed. The principle has been improved by Jimbo et al.\(^\text{209}\) who used a highly sensitive pressure measurement technique which
allowed the required solids concentration to be reduced further.

Centrifugal Sedimentation Balance. Solids sediment are placed on balance pans either in measurement cells of suitable design or in the disk rotor; the first principle is represented in Figure 27(b). On the rotor (1) there is a measurement cell (2) filled with suspension, in which there is a balance pan (3) and into which a diving body (4) is immersed. The cell (7) installed on the opposite side contains solid-free liquid. Thus, the measurement effect for the sedimenting mass is a change of pathlength measured by device (5) and supplied to the evaluation unit (6). Bürkholz et al.\textsuperscript{(210)} and Muschelknautz\textsuperscript{(175)} have reported on the development of such a balance. Similar devices with light optical scanning were introduced by Tarasov and Chodakov.\textsuperscript{(211)}

Eccentric Centrifuge. An original solution for the cumulative measurement in a sedimentation centrifuge was found by Kaya and Yokoyama\textsuperscript{(212)} the principle is represented in Figure 27(c). In the rotor (1) two measurement cells are arranged opposite each other, one of which (2) contains the suspension (solids concentration approx. 3 wt%) and the second of which (3) contains solid-free liquid. Owing to the shift of the gravity center in cell (2) caused by the sedimentation process, an eccentricity variable in time is generated leading to a deflection of the rotor shaft. The relationships between sedimenting mass and eccentricity, on the one hand, and between eccentricity and deflection, on the other hand can be described by formula\textsuperscript{(212)} For evaluation, the rotational speed of the rotor shaft has to be known (tachometer (7)) in addition to the deflection measured by parts (4) and (5). The drive (6) propels the centrifuge; the evaluation unit (8) processes the information obtained (rotational speed and deflection) to determine the searched distribution function.

In conclusion, it should be noted for the sake of completeness that single and repeated decanting is also possible in centrifuges. A typical example is the Joyce–Loebl disc centrifuge.

ACKNOWLEDGMENTS

The author thanks the Kluwer Academic Publishers for kind permission to use the Figures 6–9, 11, 13–15, 17–21, 24–27 and corresponding explanations from C. Bernhardt, \textit{Particle Size Analysis. Classification and Sedimentation Analysis}, Copyright, 1994.\textsuperscript{(13)}

SEDIMENTATION IN PARTICLE SIZE ANALYSIS

SEDIMENTATION IN PARTICLE SIZE ANALYSIS

Sieve analysis is used to obtain the particle size distribution of a solid material by determining the amount of powder retained on a series of sieves with different sized apertures. A sample is added to the top of a nest of sieves arranged in decreasing size from top to bottom. As the sieves are vibrated, the sample is segregated onto the different sized sieves. The weight of sample retained on each sieve is then used to determine the particle size distribution as well as the mean diameter of the sample.

1 INTRODUCTION

The use of sieves is the oldest and most common technique used for particle size analysis. It is generally considered to be one of the most simple, reproducible, and inexpensive methods available. Sieving can be performed on particles ranging in size from 5 μm to 125 mm. One of the main disadvantages of sieve analysis is the effect of particle shape on results. Sieving measures the smallest diameter that can pass through the opening. With irregular-shaped particles, comparison between particle size methods can be difficult. Even though comparisons of methods are not always necessary, it is often useful to obtain information about particles using several techniques based on different principles.

2 THEORY AND OPERATING PRINCIPLES

Sieve analysis is performed by segregating particles into different sized fractions on a series of sieves. The sample is placed on a nest of sieves with mesh openings decreasing in size from top to bottom. The sieves are then vibrated causing the sample to fall through the openings to a series of fractions on the individual sieves. The amount of material retained on each sieve is used to calculate the particle size distribution of the sample.\(^{(1-3)}\)

3 METHOD DESCRIPTION

3.1 Procedures

Because sieving is used for many types of materials, it is impossible to specify a single procedure. Materials vary in size, shape, density, moisture content, cohesiveness, attritability, and so on. Therefore, general procedures for dry and wet sieving are given as guidelines. American Society for Testing and Materials (ASTM) standard methods can be referenced for information on a specific type of sample.\(^{(2)}\)

3.1.1 Dry Sieving

The sieving procedure involves four basic steps: (1) sieve selection and set-up, (2) addition of sample, (3) sample fractionation, and (4) weighing retained fractions.\(^{(2)}\)

3.1.1.1 Sieve Selection and Set-up

Sieves are selected based on the size of the material to be characterized. The number of sieves should be minimized but give an accurate representation of the particle size distribution of the material. The sieves should be nested in a vertical stack with the coarsest sieve at the top and the solid pan at the bottom.

3.1.1.2 Addition of Sample

The representative sample is dried to constant weight, when possible, and weighed to an accuracy of 0.1%. The weighed sample is then placed on the top sieve and covered.

3.1.1.3 Sample Fractionation

The nest of sieves is shaken by vibration, manually, or with air pulses of sonic frequency for a specified time. A satisfactory ending time is reached when an additional one minute of sieving does not change the weight on the sieves by more than 1%.

3.1.1.4 Weighing Retained Fractions

The material on each sieve is weighed to determine the amount in each particle size fraction. For small sample sizes, the material should not be removed from the sieve. The weight in each particle size fraction can be determined by difference
PARTICLE SIZE ANALYSIS

between the ending weight of the sieve with the sample fraction and the tare weight of the sieve.

3.1.2 Wet Sieving

Wet sieving is similar to dry, however, liquid which does not dissolve the material is continually added. The wet sieving process is particularly beneficial for separation of fine particles by eliminating electrostatic and surface forces hindering particle passage under dry conditions. Typically, wet sieving is used for materials originally suspended in a liquid or for powders that agglomerate during dry sieving. Several disadvantages of wet sieving include difficulty in obtaining accurate weight measurements, error due to swelling of particles, and increased time required for drying before weighing.

Several techniques for wet sieving have been found to be effective. In general, the sample is dispersed in a liquid and placed on the sieves. Additional liquid is then added to the residue on the sieves. Acceleration of the rate of the particles moving through the sieves is possible by placing the sieves on a vibrating apparatus and/or applying vacuum to the sieves.\(^\text{(1,2)}\)

An automated wet sieving instrument has also been developed. Particles are initially placed on the finest sieves and fluidized by water. The particles that pass through the sieve are moved to a filter and weighed. After the weight remaining on the sieve has stabilized, the next larger sieve is brought into use. The procedure is continued for a series of sieves. The individual weights are then converted to weight percent data and printed.\(^\text{(4)}\)

The sieves should be chosen based upon the particle size distribution and sample quantity.

A typical sieve is a shallow pan with a wire mesh bottom or an electroformed grid. Sieves are available ranging in size from 5µm to 125mm. However, sieves are sometimes referred to by mesh size. Mesh is the nominal number of apertures. Table 1 gives details of the relationship between mesh size and aperture. Sieves used for sieve analysis are standardized according to ASTM E11 for woven wire mesh sieves and ASTM E161 for electroformed sieves.\(^\text{(1,2)}\)

Woven wire sieves have square openings and are sturdier and less expensive than electroformed sieves. Electroformed or precision sieves have special mesh made by electrodeposition of nickel rather than weaving of wire. The conical hole structure reduces particle entrapment allowing for sharper cuts in sizing. Typically, all openings in an electroformed mesh will be identical in size. These openings are either round, square or rectangular. Electroformed sieves are typically used in the very fine particle range (5–40µm).

Several types of mechanical sieve shaker are available. One type simulates hand sieving using a circular motion combined with a tapping motion. Another type uses electromagnetically induced high speed short stroke vibrations to agitate the sample causing it to flow through the sieve. A third type uses air pulses of sonic frequency to shake the sieves.

For wet sieving, the dry sieving apparatus can be modified by adding a vacuum pump.\(^\text{(1,2)}\) In addition, companies, such as Micromeritics, have developed automated wet sieving methods. Particle size separation is achieved in an oscillating and periodically advancing rotor containing sieves of various meshes.\(^\text{(4)}\)

### 3.2 Sample Preparation

Accurate sampling is a prerequisite for reliable sieve analysis. The primary cause of inconsistencies in test results is in not obtaining a sample that is representative of the entire material. Because of the wide range of materials characterized by the sieve method, it is not possible to specify a single method of sampling. Sampling should be based upon the type and form of material. One problem that occurs is segregation of particles within the sample. During transfer of material, either in a small container or railroad car, the particles tend to segregate. In ideal circumstances, the material should be well mixed and a core sample taken. If the sample quantity is small enough, it may be reduced to test sample size using a sample splitter or riffler.\(^\text{(2)}\)

### 3.3 Apparatus

Sieve measurements are performed with minimal equipment. The apparatus is made up of a balance, set of sieves, and possibly a mechanical shaker.\(^\text{(1,2)}\) The balance should be accurate to 0.1% of the sample weight.
4 INTERPRETATION OF RESULTS

4.1 Calculations

The weight of material retained on each sieve and the weight of the original test sample are used to calculate percentages. Results are normally reported in the form of percentages, not actual weights. These data are then used to calculate mean diameters, commonly referred to as average particle size. Midpoint diameters cannot be calculated for the smallest and largest fractions since the smallest and largest particle diameters are not known.

The arithmetic mean is defined as the sum of particles in a particular interval \( (n_i) \) with midpoint diameter \( (d_i) \) divided by the total number of particles (Equation 1):

\[
\text{Arithmetic mean diameter} = \frac{\sum n_i d_i}{\sum n_i} \quad (1)
\]

The geometric mean diameter (Equation 2) is the logarithmic equivalent of the arithmetic average:

\[
\log \text{geometric mean diameter} = \frac{\sum n_i \log d_i}{\sum n_i} \quad (2)
\]

In sieving, these data can also be reported as mass mean diameter or geometric mass mean diameter. The mass diameters are calculated based upon the weight of the sample rather than number of particles.

4.2 Data Representation

Particle size distribution data are presented in both tabular and graphical formats. The tabular data show the amount of material in each of the measured fractions. In addition, cumulative percent smaller than (and larger than) are often reported. An example of tabular data is presented in Table 2. These data are then graphed and used to determine the mean particle size of the material. Other fractiles, such as 10% or 90% can also be determined using this method.

The weight percent in each fraction is shown graphically in Figure 1. The weight percent is shown as a function of the midpoint diameter of the fraction given in Table 2. For example, 18% of the material is in the 40–80µm fraction, meaning 18% has been retained on the 40µm sieve. In the graph, this 18% value is plotted versus a midpoint particle diameter of 60µm. The data shown in Figure 1 indicate that the particles are skewed toward the smaller sized particles.

A second type of graph commonly used in particle size testing is shown in Figure 2. This graph shows the amount of material less than a given particle diameter. For a normal distribution, a straight line can be obtained when the particle size on a linear axis is presented on a cumulative probability scale. The cumulative distribution

![Figure 2](image2.png)  
**Figure 2** Cumulative percent less than graph.
data would then be symmetric at the 50% point. The arithmetic mean corresponds to the diameter at the 50% point.

The skewed data can be treated as a straight line if the arithmetic diameter scale is replaced with a logarithmic scale. Figure 3 illustrates the skewed data plotted on a log scale. To determine the geometric mean diameter, the diameter can be plotted as a function of cumulative weight percent less than using log-probability paper. The particle diameter extrapolated at the 50% value on the probability scale is the geometric mean diameter.

Graphical data representation is also useful in comparing samples. For example, Figure 4 shows three samples with the same mean diameter, but different types of distributions. The slope of the line is a measure of the breadth of the particle size distribution.\(^{(3)}\)

5 EFFECT OF PARTICLE SHAPE

Particle size data are based on the assumption that the particles being analyzed are spheres with uniform density. However, many samples analyzed for particle size distribution are not spherical in particle shape. Particle shape features cause different dimensional response characteristics depending upon the measuring instrument. Because of the complexity of the problem, only limited success has been made in quantifying the effect of particle shape on particle size analyzes. Since the diameter of a nonspherical particle is based upon a measured geometric parameter, the distribution of particle sizes will shift depending upon the parameter measured. The effect of shape on the particle size distribution is minimized if the shape distribution is small relative to the particle size distribution. If the particles are close to the same size, any change in shape will broaden the measured size distribution.

Particle shape is an important parameter in describing differences in results from various particle size methods. For example, comparisons have shown differences in results from sieving and laser light diffraction to be a function of particle shape.\(^{(5–8)}\) One of the most significant differences between laser light diffraction and sieving for particle size determination is the dimension of the particle measured. Light diffraction measures an average of all dimensions of the particle. With sieving, the measurement is based on the smallest diameter that can pass through the opening. With irregularly shaped particles this difference results in higher particle size measurements with laser light scattering than sieving.

Because of differences in particle size measurements as a function of particle shape, instruments are now being used to calculate particle shape factors.\(^{(9)}\) Sieves are also being used to determine particle shape distribution by measuring the rate at which particles pass through a stack of identical sieves.\(^{(10)}\)

The determination methods of the surface area and pore size distribution (PSD) of a solid have been extensively described. The surface area and PSD are important as the basic properties for a powder and porous material. Nowadays the surface area and PSD are easily obtained by an automatic measuring instrument. However, there is no method which covers the complete range of a specific surface area and a pore size. All of the methods have their limits of measurement. In many cases the definitions of the surface area and pore size in each method differ from one another. The features and principles of the methods have been discussed mainly in order to select an appropriate method and to analyze data exactly.

1 INTRODUCTION

Determination of the surface area is important for characterization of solids, especially finely divided particles and porous materials. These materials have high specific surface areas, so the surface and interface phenomena (adsorption, adhesion, aggregation, chemical reaction and dispersion in liquids) are governed by the surface area. The determination of the surface area is necessary to understand such surface and interface phenomena on solids, and to control surface properties of solids. The measurement of the surface area is performed in various industrial fields: ceramics, pigments, fillers, catalysts, electronic materials, building materials, adsorbents, food materials, cosmetics, medicine, and so on. Several methods for determining the surface area are described in this article; however it is noticed that the definition of surface area differs from one method to another. Therefore the researcher should understand the principles of the determination methods and select an appropriate method.

Determination of the PSD of porous solids is important for porous structure analyses. Porous structures affect adsorption property, permeability, diffusion of gases and ions, thermal conductivity, strength, and so on. Many determination methods of the PSD have been proposed, and commercial apparatus is available. However, the researcher should note the following: most methods assume the simple pore model, for example the cylindrical pore model, but this is quite different from real pore structures; and all the methods have a lower and upper limit of detection for the pore size. In analogy with surface area determination, the selection or combination of methods and the understanding of methodology are important. Studies about the determination of the PSD are still being carried out. The current topics are available in the Proceedings of the Characterization of Porous Solids, (1–4).

2 DETERMINATION OF SURFACE AREA

2.1 Gas Adsorption Method

The determination of the surface area by gas adsorption is one of the most reliable methods, and is widely used for powders and porous materials. It is necessary for the adsorption method to estimate monolayer capacity ($V_m$) of an adsorbate and cross-sectional area ($\sigma$) of an adsorbed molecule. The specific surface area ($S$; the surface area of 1 g of the solid) is given by Equation (1):

$$S = V_m\sigma N_A$$

(1)

where $V_m$ is expressed in moles per gram of the solid and $N_A$ is the Avogadro number. Monolayer capacity is usually estimated from the adsorption isotherm by the
Brunauer–Emmet–Teller (BET) method. The BET equation is shown in Equation (2):

\[
V = V_m \frac{CX}{(1-X)(1-X+CX)}
\] (2)

where \(V\) is the amount of gas adsorbed, \(C\) is a constant value and \(X\) is the relative pressure: \(P/P_0\) (\(P\), equilibrium pressure and \(P_0\), saturated vapor pressure). Usually Equation (2) can be rewritten for plotting experimental data as Equation (3):

\[
\frac{X}{V(1-X)} = \frac{1}{V_mC} + \frac{(C-1)X}{V_mC}
\] (3)

The plot of \(X/V(1-X)\) against \(X\) is called the BET plot, which is usually linear in the range of 0.05 < \(X\) < 0.35. It should be noted that the relative pressure range in which the BET plot shows linearity depends on the kind of adsorbates and solids. The value of \(V_m\) and \(C\) are calculated from the slope and intercept of the BET plot. The adsorption isotherm of nitrogen and the BET plot are shown in Figure 1. The constant \(C\) is represented by Equation (4):

\[
C \cong \exp \left( \frac{Q_1 - Q_L}{RT} \right)
\] (4)

where \(Q_1\) is the isosteric heat of adsorption of molecules in the first layer and \(Q_L\) is the heat of condensation of the liquid adsorbate. The constant \(C\) represents the interaction between the adsorptive molecule and solid surface qualitatively. Thus the shape of the adsorption isotherm depends on the constant \(C\). The adsorption isotherms deduced by the BET equation are shown in Figure 2.

The cross-sectional areas (\(\sigma\)) of adsorbed molecules have been calculated by various methods. Usually the \(\sigma\)-value is estimated from the liquid density (\(d\)) of the adsorbate at the working temperature, using Equation (5):

\[
\sigma = F \left( \frac{M}{N_A d} \right)^{\frac{2}{3}}
\] (5)

where \(F\) is the packing factor and \(M\) is the molecular weight of the adsorbate. The packing factor \((F)\) is determined by the coordination number of adsorbed molecules on solid surfaces and in the adsorbed layer. If the liquid structure of the adsorbate is the closest packing structure with 12 nearest neighbors, and the adsorptive molecules are adsorbed on the surface with 6 nearest neighbors in the close-packed hexagonal arrangement, the value of \(F\) is 1.081. Usually the adsorption gas used for the surface area determination is nitrogen, because nitrogen molecules can form a monolayer at 77 K on various solids. The \(\sigma\)-value for the nitrogen molecule is 0.162 nm\(^2\). In the case of nitrogen adsorption, if \(V_m\) is

![Figure 1 Adsorption of nitrogen on porous silica glass at 77 K: (a) adsorption isotherm; (b) BET plot.](image1)

in milliliters at standard temperature and pressure per gram, the specific surface area can be estimated using Equation (6): 

$$S (\text{m}^2 \text{g}^{-1}) = 4.35 V_m$$

McClellan and Harnsberger$^{(8)}$ have produced a table of the $\sigma$-values for about 106 compounds. The average $\sigma$-values of several molecules calculated from adsorption data are summarized in Table 1. Generally the surface areas determined by nitrogen adsorption differ from those estimated from adsorption of other gases. Several reasons for these differences are given: change in the $\sigma$-value due to orientation of the adsorbate molecule, the validity of the BET equation, and so on. One of the reasons is attributed to the difference in the accessibility of the adsorptive molecule to surface geometry. Consequently the surface areas depend on the size of probe molecules. Avnir et al.$^{(9)}$ have derived the fractal dimension ($D$) of solid surfaces from the adsorption of various gases on solid surfaces.

Usually nitrogen gas is used to measure the surface area. However, for the measurement of very small surface areas, adsorption of krypton$^{(10-13)}$ or xenon$^{(14-16)}$ gases at low temperature (77 K or 83 K) are used. The vapor pressure of these gases at 77 K is very low, so the correction of the vapor pressure is required for the thermal transpiration effect.$^{(17)}$

A lot of commercial apparatus is available for surface area determination by gas adsorption measurement. This apparatus is classified into three categories: volumetric method, carrier gas method (dynamic method) and gravimetric method. Adsorption measurement by quartz crystal microbalance (QCM)$^{(18,19)}$ or surface acoustic wave (SAW)$^{(20-22)}$ devices are some of the new techniques for surface area determination. The principle of these techniques is based on the change in oscillation frequency of the quartz or the SAW oscillator, according to the change in surface mass density. The relationship between the change in oscillation frequency ($\Delta f$) of the oscillator and the change in surface mass density ($\Delta W$) using the quartz oscillator is shown in Equation (7):

$$\Delta f = -f_0 \frac{\Delta W}{NA\rho}$$

where $f_0$ is the parent frequency, $N$ is the frequency constant for AT-cut quartz ($1.67 \times 10^6$ Hz mm), $A$ is the area of the electrode, and $\rho$ is the density of quartz (2.648 g cm$^{-3}$). The sensitivity of a 10 MHz QCM is 5 ng cm$^{-2}$. The QCMs or SAW devices are capable of measuring nitrogen adsorption on thin films. Commercial volumetric or gravimetric adsorption apparatus cannot obtain nitrogen adsorption data of such low surface area materials. These techniques are applicable to estimate the pore structure analysis by gas adsorption (see section 4.1).

### 2.2 Liquid Adsorption Method

The principle of the determination of surface area by liquid adsorption is the same as that by gas adsorption. Dyes$^{(23-28)}$ or fatty acids$^{(29-31)}$ in solution are frequently used as a probe molecule for the surface area determination. The liquid adsorption method is easy to operate and does not need special apparatus compared to the gas adsorption method. However it is necessary to estimate the cross-sectional area of an adsorptive molecule and the effect of solvent. Because a cross-sectional area of an adsorptive molecule depends on the configuration of an adsorbed molecule, competitive adsorption of adsorptive molecules between solvent molecules occurs. So the solutes (adsorptives) and solvents should be carefully selected for the sample solid. The liquid adsorption isotherm is represented by a plot of the amount of adsorbed vs the equilibrium concentration of the adsorbable. Several equations for the liquid adsorption isotherm have been proposed: the Henry equation, the Langmuir equation, the Frumukin equation and the Freundlich equation. The Langmuir equation is frequently used to determine the monolayer capacity. The equation is expressed by Equation (8):

$$V = \frac{AV_mC}{1 + AC}$$

where $A$ is a constant. The expression for plotting experimental data is given by Equation (9):

$$\frac{C}{V} = \frac{1}{V_mA} + \frac{C}{V_m}$$

The monolayer capacity is obtained from the slope of the plot of $C/V$ against $C$. Figure 3 shows adsorption isotherms of several dyes on charcoal.$^{(24)}$ The cross-sectional areas of dye molecules$^{(32)}$ are shown in Table 2. In the case of dye adsorption, the formation of molecular aggregates in high concentration and the effect of
pH on adsorption should be noted. The concentration of dye solution is determined from the measurement of absorbance of the solution by ultraviolet/visible spectrometer. The dye adsorption method is applicable to measure low surface area (\( \text{\textgreek{m}}^2 \text{g}^{-1} \)). However, accessibility of dye molecules to internal surfaces should be considered because the size of dye molecules is large compared to that of gas molecules, which are usually used as probe molecules for surface area determination.

In the case of fatty acid adsorption, steric acid in organic solution (ethanol, hexane, and benzene) is frequently used. The organic solvents should be dehydrated. The cross-sectional area of steric acid is estimated by the titration method. The direct adsorption of ethylene glycol is used to determine the surface area of clay minerals.\(^{28,33–35}\) The cross-sectional area of an ethylene glycol molecule is assumed to be 0.224 \(\text{nm}^2\).

2.3 Permeametry

Surface area determination by permeametry is used for powder materials. This method is characterized by simple apparatus, easy operation and rapid measurement compared to the other method. Permeametry is based on fluid flow through a packed powder bed (porous media). The specific surface area is calculated from the Kozeny–Carman equation, shown in Equation (10):

\[
S_w = \frac{1}{\rho} \left\{ \left( \frac{\Delta P_t A}{k \eta L V} \right) \frac{e^3}{(1 - e)^2} \right\}^{\frac{1}{2}} \tag{10}
\]

where \(S_w\) is the specific surface area of the sample powder, \(\rho\) is the true density of the sample powder, \(\Delta P\) is pressure drop, \(t\) is time, \(A\) is the cross-sectional area of the powder bed, \(k\) is the Kozeny constant, which is usually assumed to be 5, \(\eta\) is the viscosity coefficient of the fluid, \(L\) is the length of the powder bed, \(V\) is the volume of fluid passed through powder bed during time \(t\), and \(e\) is the porosity of the powder bed. The surface area of the powder bed can be calculated from measurement of the flow rate \(V/t\) and pressure drop \(\Delta P\). Gases and liquids can be used as the flowing fluids; however, gases (air or He gas) are usually used, rather than liquids, in order to avoid a dissolution of samples and reconstruction of the powder bed. The many equations for permeametry based on the Kozeny–Carman equation have been derived to fit the experimental procedure, and many types of apparatus have been proposed.\(^{36–41}\) The Blaine apparatus and the Fischer Sub-Sieve Sizer apparatus\(^{42}\) are typical for air permeametry. This apparatus is commercially available. The surface area thus obtained means the external surface area and does not include internal surface: micropores and cracks. Equation (10) is applicable only in the viscous flow condition, so this analysis is limited to coarse powder particles (\(\sim 2 \mu m\)).

When the particle size of the powder bed becomes smaller (\(\sim 1 \mu m\)), the gas flow mechanism changes from viscous flow to Knudsen flow, which is controlled by the rate of molecular diffusion. Carman modified Equation (10) by considering the Knudsen flow and derived the general equations shown in Equations (11) and (12):

\[
\frac{V'L}{\Delta PA} = \left( \frac{P'}{5 \eta S_w^2 RT} \right) \frac{e^3}{(1 - e)^2} + \left( \frac{4Z}{3} \right) \left( \frac{v}{S_w} \right) \left( \frac{e^2}{1 - e} \right) \tag{11}
\]

\[
\rho S_w = S_e \tag{12}
\]

where \(V'\) is the velocity (moles per second) of fluid gas, \(P'\) is the average pressure in the powder bed, \(Z\) is a constant, and \(v\) is the rate of molecular diffusion. The first term of the right-hand side is the contribution of viscous flow and the second term is that of the Knudsen flow. The plot of \(V'L/\Delta PA\) vs \(P'\) should be linear. The surface area calculated from the slope of the linear line corresponds to the external surface area. However, the surface area estimated from the intercept represents the total surface area of the powder sample. The constant \(Z\) depends on
the shape of the path. The Z value is experimentally determined to be 0.45 or 0.47. Several other studies on permeametry in the Knudsen flow condition have been reported.\(^{(37,38,43,44)}\)

### 2.4 Other Methods

#### 2.4.1 Microscopic Method

If the powder samples have no pores, the specific surface area of solids is estimated from the size of the primary particle as shown in Equation (13):

\[
S = \frac{K}{\rho l}
\]

where \(S\) is the specific surface area of the solid, \(K\) is the shape factor, \(\rho\) is true density of the particle, and \(l\) is the size of the particle. If the particle shape is cubic or spherical, the constant \(K\) is 6 and \(l\) represents the edge length of the cubic particle or the diameter of the spherical particle. Usually the size of the primary particle, \(l\), is determined using optical or electron microscopy.

#### 2.4.2 Heat of Immersion Method

When a solid surface is immersed in liquid which does not dissolve the solid, heat which is termed the heat of immersion is evolved. Harkins and Jura\(^{(45)}\) developed an “absolute method” to estimate the surface areas of powders using the measurement of heat of immersion. When the sample powder with the liquid adsorbed layer is immersed in the adsorptive liquid, the heat of immersion is attributed to the total surface energy of the adsorptive liquid. The surface area \((S)\) is represented by Equation (14):

\[
S = \frac{Q}{h_L}
\]

where \(Q\) is the heat of immersion and \(h_L\) is the enthalpy per unit surface area of the adsorption liquid. In the case of water, a two-molecule-thick adsorbed layer on a solid surface is sufficient to measure\(^{(46)}\) and \(h_L\) is 118 erg m\(^{-2}\).

### 3 CLASSIFICATION OF PORE SIZES AND PORE STRUCTURE

Pores are classified into three types, based on their sizes, according to the IUPAC recommendation:\(^{(47)}\)

- **Macropores**: \(d(w) > 50\text{ nm}\)
- **Mesopores**: \(2\text{ nm} < d(w) < 50\text{ nm}\)
- **Micropores**: \(d(w) < 2\text{ nm}\)

where \(d\) and \(w\) mean a pore diameter and a pore width, respectively. Many methods for determining the PSD of porous materials have been proposed. However, there is no experimental technique covering the whole range of pore size. Hence, it is important to choose methods appropriate for the pore size. It should be noticed that each method has a detection limit for the pore size. The applicable range of pore size for PSD analysis methods described in this chapter is shown in Figure 4.

Figure 5 shows a model of pores in a solid. The pore structure is mainly classified into two categories: closed pores (a) and open pores (b–h). The open pores consist of several types: through pores (b) are open at two ends, blind pores (c) are open only at one end, independent pores (b, c) do not connect with other pores and crossing pores (d) connect with other pores. From the viewpoint of pore shape, pores are classified as follows: cylindrical pores (e), conical pores (f), ink-bottle pores (g), slit pores (h), and so on. The consideration of the origin of pores is useful for the understanding of pore structure. The pores in zeolite, which is well-known as a...
PARTICLE SIZE ANALYSIS

molecular sieve and catalyst, originate from the crystal structure. The slit pore in layered materials such as clay minerals and graphite is in this category. These pores are characterized by a regular structure. Some pores can be prepared by the removal of substances dispersed in a solid beforehand. Porous silica glass is prepared by the dissolution of a separated Na2O–B2O3 phase in the SiO2 matrix. The mesoporous silica MCM-41 is prepared by the micelle template. Silica gel containing organic polymer can form pores by calcination. The size and structure of pores originated from the removal of additives in a solid depend on the dispersion condition and size of additives. The aggregation of small particles forms voids (pores) between the particles. These pore structures depend on the particle size and its distribution, particle shape and packing structure. The sintered body and silica gel are attributed to this structure.

4 DETERMINATION OF MACROPORE AND MESOPORE SIZE

4.1 Gas Adsorption Method

4.1.1 Capillary Condensation Method

Generally the adsorption isotherm of gas on a mesoporous solid shows the Type IV isotherm in the IUPAC classification of adsorption isotherms. The Type IV isotherm is shown in Figure 6. The adsorption isotherms on a mesoporous solid show a steep increase in the amount adsorbed due to capillary condensation, and a steep decrease in the adsorbed amount due to capillary evaporation. Consequently, the adsorption isotherm has a hysteresis loop. The capillary condensation method for the determination of PSDs is based on the relationship between the pressure at which capillary condensation occurs and the pore radius. This relationship is represented by the well-known Kelvin equation, shown in Equation (15):

$$r_k = \frac{-2\gamma V_m \cos \theta}{RT \ln(P/P_0)}$$

where \(r_k\) is the Kelvin radius, and \(\gamma\) and \(V_m\) are surface tension and molar volume of the condensate, respectively, \(T\) is a measuring temperature, \(\theta\) is a contact angle between the condensate and the pore wall, and \(P/P_0\) is the relative pressure at which capillary condensation occurs. Usually \(\theta\) is assumed to be zero, so Equation (15) is simplified to Equation (16):

$$r_k = \frac{-2\gamma V_m}{RT \ln(P/P_0)}$$

When capillary condensation occurs, the thickness of a layer already adsorbed on the pore walls is given by \(t\). Consequently the pore radius is given by Equation (17):

$$r_p = r_k + t$$

In the case of nitrogen adsorption, many studies on the thickness of the adsorbed layer have been reported. Several equations for the relationship between the thickness of the adsorbed layer and relative pressure have been proposed for computation. Dollimore and Heal recommended the use of Equation (18):

$$t (\text{nm}) = 0.35 \left[ \frac{-5}{\ln(P/P_0)} \right]^{\frac{1}{3}}$$

A number of calculation methods for the determination of PSDs based on the Kelvin equation (e.g. Barret–Joyner–Halenda (BJH) method, Dollimore–Heal (DH) method) have been proposed, however, the principle of the computation procedure is almost the same. The calculation of PSDs is performed according to the following concept. The amount \((\Delta V)\) decreased in a desorption step is represented by the sum of the amount \((\Delta V_c)\) of capillary evaporation, and the amount \((\Delta V_m)\) of multilayer desorption from the pores in which capillary evaporation has already occurred, as shown in Equation (19):

$$\Delta V = \Delta V_c + \Delta V_m$$

The capillary condensation method is widely used for the determination of PSDs of mesoporous solids, and automatic measuring apparatus is commercially available. However, it should be noticed that this method has several
Kelvin equation in small pores have been reported. It is clear that this model is quite different from real porous structures. Second, as mentioned above, the adsorption isotherm on mesoporous solid shows a hysteresis loop. It should be noticed whether the calculation is performed on the adsorption or desorption branch of the hysteresis loop. Equation (15) is adopted for analysis of the desorption branch. When the adsorption branch is used for analysis, the Kelvin equation shown in Equation (20) is used:

\[ r_k = \frac{-\gamma V_m}{RT \ln(P/P_0)} \]  

(20)

This problem is very important, because the PSD depends on which branch of the hysteresis loop is used for the calculation. Further study, including the origin of the hysteresis loop, is required. The lower and upper pore size limits of the capillary condensation method are obscure. In a small pore it is expected that the physical properties of capillary condensed liquids are different from those of bulk liquids. Hence, the calculation of the pore radius by the Kelvin equation using the bulk values of surface tension and molar volume of condensates is inadequate for small pores. The criticisms on the application of the Kelvin equation in small pores have been reported. The development of idealized mesoporous solids such as MCM-41 and the progress in computer chemistry of adsorption simulation will be expected to refine the capillary condensation method in the small pore size region. However, the upper pore size limit depends on the accuracy of the adsorption measurement. The relationship between relative pressure and the pore radius is shown in Table 3. Clearly it is difficult to analyze macropore sizes with high precision compared with mesopore sizes.

### 4.1.2 Comparison Plot Method

The comparison plot method is one of the pore-structure analyses and reveals the existence of micropores and mesopores. Two kinds of comparison plots have been proposed: the t-plot developed by Lippens and de Boer and the \( \alpha_s \)-plot by Sing. Both plots are obtained by comparison of the nitrogen adsorption isotherm on the sample with that on a standard solid. The standard solid should be equivalent to the sample solid and have no pores. In the case of the t-plot, the relationship between the relative pressure and the thickness of the adsorbed layer for the standard solid is required. The thickness \( t \) of the adsorbed layer of nitrogen is calculated from Equation (21):

\[ t (\text{nm}) = \frac{0.354 V}{V_m} \]  

(21)

where \( V \) is the amount adsorbed, and \( V_m \) is the monolayer capacity. Standard data are shown in Table 4. The t-plot of the sample is obtained by converting the relative pressure of the adsorption isotherm on the sample into the thickness of the adsorbed layer of nitrogen, according to the standard data. Models of t-plots are shown in Figure 7. When the sample has no pores, the t-plot gives a straight line. The specific surface area \( S_t \) is calculated from the slope of the t-plot using Equation (22):

\[ S_t = \frac{1.547 V}{t} \]  

(22)

If the sample has mesopores, the t-plot deviates upwards from a straight line, due to capillary condensation.

</tbody>
</table>
the pore fills with the adsorbate, the slope of the t-plot is gradual. The external surface area of the sample is estimated from the slope of this part. If the sample has micropores, the t-plot again deviates downwards from a straight line, due to micropore filling. The disadvantage of the t-plot is the uncertainty of the thickness below the monolayer (<0.354 nm). The $a_s$-plot was developed to improve this disadvantage. The $a_s$-value is defined instead of the t-value, as shown in Equation (23):

$$a_s = \frac{V}{V_{0.4}}$$

(23)

where $V_{0.4}$ is the amount adsorbed at $P/P_0 = 0.4$. Standard data are shown in Table 4. The plot of $V$ against $a_s$ is called the $a_s$-plot. Basically, the interpretation of the $a_s$-plot is similar to that of the t-plot. The specific surface area ($S_{as}$) is represented by the slope of the $a_s$-plot, as shown in Equation (24):

$$S_{as} = \frac{2.89 V}{a_s}$$

(24)

The $a_s$-plot is especially useful to determine the surface area of microporous materials.\(^{77,78}\)

4.2 Mercury Porosimetry

Mercury porosimetry is based on the fact that excess pressure is required to cause the intrusion of mercury, which is the non-wetting liquid for most of the materials into the pore. The relationship between the pressure and the pore radius is expressed by the Washburn equation shown in Equation (25):

$$r = \frac{-2\gamma \cos \theta}{P}$$

(25)

where $r$ is the pore radius, $\gamma$ is the surface tension of mercury, $\theta$ is the contact angle between mercury and the pore wall, and $P$ is the excess pressure. The surface tension of mercury is 485 dyn cm$^{-2}$ and $\theta$ is usually assumed to be 140°. So Equation (25) can be expressed by Equation (26):

$$r (\mu m) = \frac{107.7}{P (psi)}$$

(26)

One feature of mercury porosimetry is that it is capable of estimating the size of a wide range of pores (from mesopores to macropores). It is especially useful for determining the macropore size range, because there are few methods applicable to analysis of macropores. The lower-limit pore size and upper-limit pore size depend on the pressures which the apparatus can achieve. Nowadays commercially available apparatus can work at 60000 psi, so the measurable pore size range is between 1.8 nm and 108 $\mu m$ (if the minimum pressure is 1 psi). Usually a value of 140° as the contact angle is used for computation; however, it is predicted that the contact angle is affected by the surface chemical composition and the surface roughness.\(^{79}\) The contact angle at atmospheric pressure will differ from that at high pressures. A change in contact angle by 10° from 140° causes a change in pore size of 16%. The problem of contact angle should be discussed in the future. Destruction or deformation of the sample is caused by compression. Reversible deformation should be corrected. However, irreversible deformation or destruction is seriously affected by the PSDs. The sample which amalgamates with mercury is unsuitable for this method. Contamination by amalgam causes a change in contact angle and surface tension of mercury. Intrusion–extrusion curves of mercury porosimetry are shown in Figure 8. Intrusion–extrusion curves frequently display a hysteresis loop. Several reasons for the occurrence of the hysteresis loop have been proposed: the difference in contact angles at intrusion and
extrusion\(^{(80,81)}\) the geometrical shape of individual pores (e.g. “ink-bottle” type pore); and the network effect of pores. The morphology\(^{(82)}\) and pore connectivity\(^{(83)}\) have been estimated from the hysteresis loop.

If a non-wetting liquid is used for the sample solids, the principle of mercury porosimetry can be applied to other liquids. Recently, water porosimetry for hydrophobic materials has been attempted.\(^{(84)}\)

### 4.3 Thermoporometry

Thermoporometry is based on calorimetry of the liquid–solid transition of a condensate confined in pores. It is well known that the freezing and melting points of liquids confined in pores decrease with decrease in the pore size. Brun et al.\(^{(85)}\) developed a method of determining PSDs from a solidification thermogram by means of theoretical relationships. The relationship between the depression of the freezing or melting point \((\Delta T)\) of water and pore radius \((r_p)\) is given by Equation (27) for freezing and Equation (28) for melting:

\[
\begin{align*}
    r_p (\text{nm}) &= - \left( \frac{64.67}{\Delta T} + 0.57 \right) \\
    r_p (\text{nm}) &= - \left( \frac{32.33}{\Delta T} + 0.68 \right)
\end{align*}
\]

The pore volume is estimated from the apparent energy \((W_a)\) of freezing or melting of water. These values are obtained for freezing from Equation (29) and for melting from Equation (30):

\[
\begin{align*}
    W_a (\text{J g}^{-1}) &= -5.56 \times 10^{-2} \Delta T^2 - 7.43 \Delta T - 332 \\
    W_a (\text{J g}^{-1}) &= -0.155 \Delta T^2 - 11.39 \Delta T - 332
\end{align*}
\]

Usually water is used as the condensate in pores, because water shows a larger latent heat at the liquid–solid transition as compared to other condensates. However, some organic liquids used as condensate for thermoporometry have been reported: benzene,\(^{(85)}\) undecane,\(^{(86,87)}\) decane,\(^{(88)}\) and paranitrophenol.\(^{(89)}\) These organic liquids are useful for the measurement of the hydrophobic materials and overambient measurements.\(^{(89)}\) The dependence of melting points of water and benzene on pore radius is shown in Figure 9.\(^{(85)}\) The advantage of thermoporometry is that pore analysis can be performed in wet environments. Thermoporometry is appropriate for the analysis of wet gels\(^{(90,90)}\) and polymeric ultrafiltration (UF) membranes.\(^{(91–93)}\) The pore shape or structure of aggregates of these materials changes with the drying process. Thermoporometry can be used for rigid porous materials.\(^{(94,95)}\) Several methods of determining PSDs based on the liquid–solid transition have been proposed.\(^{(96–99)}\) The thermograms are obtained using a dilatometer or differential scanning calorimeter, and are measured at a slow scanning rate \((0.1–1 \text{ K min}^{-1})\) in order to maintain equilibrium.

The freezing/melting transition of water, benzene and cyclohexane confined in porous materials has been measured by \(^1\text{H}-\text{NMR}\) (nuclear magnetic resonance).\(^{(100)}\) The PSD has been derived from \(^1\text{H}-\text{NMR\ signal intensity vs temperature curves of the confined liquids in the pores. The liquid–solid transition in pores is estimated from the \(^1\text{H}-\text{NMR signal intensity.}}}

### 4.4 Other Methods

#### 4.4.1 X-ray Scattering Method

Porous materials have differences in electron density (solids and voids), so small-angle X-ray scattering (SAXS) occurs. The Guinier equation is represented by Equations (31) and (32):

\[
\begin{align*}
    I(Q) &= I_0 \exp \left( -\frac{R_G^2 Q^2}{3} \right) \\
    Q &= \frac{4\pi \sin \theta}{\lambda}
\end{align*}
\]

where \(I(Q)\) is the strength of scattering, \(I_0\) is a constant, \(R_G\) is the gyration radius of the pore, \(Q\) is the scattering parameter, and \(\lambda\) is the wavelength of the X-ray. If the pore is spherical, the pore radius \((r)\) is related to \(R_G\) by Equation (33):

\[
R_G = \left( \frac{3}{5} \right) \frac{1}{r}
\]

According to this method the size of closed pores can be estimated.
5 DETERMINATION OF MICROPOROUS SIZE

5.1 Dubinin–Radushkevich Method

The Dubinin–Radushkevich (DR) method is based on the analysis of the gas adsorption isotherm. The gas adsorption isotherm on microporous solids shows a Type I isotherm (Figure 10). The Type I isotherm is called the Langmuir type, which is frequently observed during chemisorption. However, in the case of physisorption on microporous solids, the origin of the shape of the adsorption isotherm is due to micropore filling. The micropores tend to fill with adsorbate at low relative pressures. The adsorption isotherm on the microporous solids is described by the DR equation shown in Equations (34) and (35):

$$W = W_0 \exp \left( -B \left( \frac{T}{\beta} \right)^2 \log^2 \left( \frac{P}{P_0} \right) \right)$$ (34)

$$E_0 = \frac{0.01915}{B^{1/2}}$$ (35)

where $W$ is the volume of micropores filled at relative pressure $P/P_0$ and temperature $T$, $W_0$ is the total volume of micropores, $B$ is the so-called structural constant, the parameter $\beta$ is the affinity coefficient, which depends on the adsorptive $[\beta(C_6H_6) = 1]$, and $E_0$ is the characteristic energy of adsorption. Equation (34) is rewritten for experimental use as Equation (36):

$$\log W = \log W_0 - D \log^2 \left( \frac{P}{P_0} \right)$$ (36)

A plot of $\log W$ against $\log^2(P_0/P)$ is called a DR plot and the total volume of micropores is calculated from the intercept. A DR plot is shown in Figure 11. The characteristic dimension of the micropore ($x$), corresponding to the half width of the slit pore, is related to the characteristic energy of adsorption ($E_0$) by Equation (37):

$$x = \frac{k}{E_0}$$ (37)

where the value of the parameter $k$ depends on $E_0$. When the value of $E_0$ is $22-14 \text{kJ mol}^{-1}$, the value of $k$ is $12.5-12.9 \text{kJ nm mol}^{-1}$.

5.2 Horvath–Kawazoe Method

Horvath and Kawazoe theoretically determined an average potential function inside the slit-shaped pore model. Equation (38) is the general expression of the Horvath–Kawazoe (HK) equation:

$$RT \ln \left( \frac{P}{P_0} \right) = \frac{K}{\sigma^4(l-2\delta)} - \frac{\sigma^4}{3(l-\delta)^3} - \frac{\sigma^{10}}{9(l-\delta)^9} + \frac{\sigma^{10}}{96^9}$$ (38)

where $P/P_0$ is the relative pressure, parameter $K$ depends on the properties of adsorbent and adsorbate, $\sigma$ is the distance between a gas atom and the surface at zero interaction energy, $2\delta$ is the sum of the molecular diameter of adsorbed molecules and the atomic diameter of solid atoms, and $l$ is the distance between the nuclei of the parallel layers (Figure 12). Consequently, the effective pore size ($w$) is given by Equation (39):

$$w = l - \delta_s$$ (39)

where $\delta_s$ is the diameter of solid atoms. In the case of the nitrogen adsorption in slit-shaped pore (graphite), Equations (38) and (39) are given by Equations (40)

---

Figure 10 Model of Type I adsorption isotherm.

Figure 12 Model of a slit-shaped pore.

and (41):

\[
\ln \left( \frac{P}{P_0} \right) = \frac{62.38}{l - 0.64} \frac{1.859 \times 10^{-3}}{(l - 0.32)^3} \\
- \frac{2.7087 \times 10^{-7}}{(l - 0.32)^9} - 0.05014
\]

(40)

\[
w = l - 0.34
\]

(41)

where \(l\) and \(w\) are in nanometers. The effective pore sizes corresponding to the relative pressures are shown in Table 5. The HK equation has extended the other systems. Swiatkowski et al.\(^{107}\) deduced the equations for benzene– and argon–carbon systems. These are shown in Equations (42) and (43), respectively:

\[
\ln \left( \frac{P}{P_0} \right) = \frac{72.619}{l - 28} \frac{2.874 \times 10^{-3}}{(l - \delta)^3} \\
- \frac{7.67 \times 10^{-7}}{(l - \delta)^9} - 0.05567
\]

(42)

\[
\ln \left( \frac{P}{P_0} \right) = \frac{62.38}{l - 25} \frac{1.859 \times 10^{-3}}{(l - \delta)^3} \\
- \frac{2.7087 \times 10^{-6}}{(l - \delta)^9} - 0.05014
\]

(43)

The HK equation has been extended to argon adsorption in cylindrical\(^{108}\) and spherical pores\(^{109}\) of zeolites.

5.3 Other Methods

5.3.1 Comparison Plot Method

The comparison plot method is described in section 4.1.2.

5.3.2 Molecular Probe Method

The molecular probe method is based on the molecular sieving abilities of micropores. The effective pore size can be estimated from the adsorption capacities of a series of molecules varying in size and shape.\(^{110,111}\)

5.3.3 Nuclear Magnetic Resonance Method

The chemical shift of NMR spectra reflects the local environment of the observed nucleus. \(^{129}\)Xe NMR of adsorbed Xe in micropores has been developed to study the local environment in pores.\(^{112–114}\)

The size of particles in a suspension can be estimated by measuring the turbidity of the suspension. Turbidity measures the attenuation of a beam of light traveling through the suspension caused by the scattering and absorption of light by the particles. The amount of scattering and absorption depends on the size of the particles and their concentration in the suspension. Most of the reported applications in the literature use turbidimetry for the estimation of the particle size distribution (PSD) or an average size for particles with diameters ranging from 0.035 to 50 µm. Turbidimetric techniques are low cost, experimentally simple, fast, nondestructive and require no calibration. They are robust methods with very good reproducibility and can be used either off- or on-line, in a laboratory or a plant environment. They have been used for particle or droplet size determination in a variety of diverse systems such as latex particles, silver bromide sols and cow’s milk. Most of the time common ultraviolet/visible (UV/VIS) spectrophotometers are utilized for the turbidity measurements. Certain modifications may be necessary on these instruments depending on the size of the particles. The turbidity of the suspension is measured and the size of the particles or the PSD is estimated utilizing light scattering theory. For spherical isotropic homogeneous particles and absence of multiple scattering this theory is well established. The extension to nonspherical and inhomogeneous particles is a field of active research yielding numerous publications.

A controversy existed in the literature regarding the capability of turbidimetry to provide the full PSD but has now been resolved. For polydisperse suspensions, for certain combinations of particle sizes and optical properties, the method cannot provide the full PSD, but only an average size of the PSD. This limitation is simply a result of the light scattering patterns and it is expected theoretically. In some cases it can be overcome by simply altering the optical properties of the suspension (i.e. choosing the proper wavelengths for the turbidity measurements or a medium with a different refractive index to suspend the particles). To make the best use of the method and interpret the results in a meaningful way
one should be aware of this limitation and work with it. When this is done, excellent results can be achieved. The advantages of the method and a good knowledge of its capabilities make it a very robust choice for many applications. The numerous reports from the successful application of the method are a testimony to this.

1 INTRODUCTION

Turbidimetry refers to a group of techniques that utilize either turbidity measurements at different wavelengths, or a combination of measurements of turbidity and of the particle volume fraction, to estimate the size of particles in suspensions. Turbidity measures the attenuation of a beam of light when it passes through a suspension of particles. Using light scattering theory this attenuation can be theoretically related to the size and concentration of particles in the suspension if the optical properties (refractive indices of particles and medium) are known. For spherical particles and absence of multiple scattering this theory is well established. Extensions to nonspherical particles have been reported. Simple UV/VIS spectrophotometers can be modified (and in some cases used as bought) for the turbidity measurements. Wavelengths in the near-infrared (NIR) range can also be utilized. Particle sizes from the lower submicrometer range to many micrometers can be measured with the proper choice of wavelength for the turbidity measurements. Applications of turbidimetry for particle size determination have been reported mainly for particles with diameters between 0.035 and 50 µm. The simplicity of this fast, noninvasive method, its low cost, good reproducibility and the wide range of particle sizes that it covers have made it very attractive for particle size determination. Mainly owing to its simplicity, the method is robust and suitable for industrial production environments as an on-line particle size determination method.

The first attempts to use turbidimetry for particle size determination started in the 1950s. At the time workers tried to use approximation theories1 or tabulate turbidity functions2,3 mainly owing to a lack of powerful computing machines. Ever since, there has been an abundance of reports on the use of turbidimetric techniques for the determination of particle size in a variety of systems, such as silver bromide sols in water,4–6 polystyrene latexes7,8 poly(vinyl acetate) latexes9–15 homogenized milk and oil-in-water emulsions16–18 coupler dispersions19 and minerals.20 A wide range of wavelengths in the UV/VIS region have been utilized for the turbidity measurements but also work in the NIR region has been reported6,16,17,19. The determination of particle size using on-line turbidimetry has also attracted a lot of attention.6–11,15,21–24 Some of the work reported in the literature for particle size determination in polydisperse systems (full PSD or an average diameter) for different materials is given in Table 1.

A controversy in the literature11,12,31 regarding the capability of turbidimetry to provide the full PSD has been resolved by a theoretical analysis and experimental verification reported in Kourt et al.15,32 The results can be summarized as follows.

The capability of turbidimetric techniques to provide an average particle size or the PSD of a suspension and their sensitivity to experimental error cannot be generalized across refractive indices and particle size ranges. It depends on the optical properties of the suspension and the size of the particles relative to the wavelength and conclusions cannot be extrapolated from one optical regime and particle size to another and from one technique to another. For monodisperse suspensions the particle size can always be estimated using turbidimetry, provided that two turbidity measurements at widely separated wavelengths together with a measurement of the particle volume fraction in the suspension is used. This is irrespective of the optical properties of the suspension (refractive indices of particles and medium, wavelength of light) and the size of the particles. In some simpler cases only two turbidity measurements or measurement of one turbidity and the volume fraction are sufficient. For polydisperse suspensions, turbidity measurements at sufficient wavelengths (the number depends on the detail of the PSD one wishes to resolve) together with a measure of the particle volume fraction are required for the determination of the full PSD. However, for certain combinations of particle sizes and optical properties, the method cannot provide the full PSD, but only an average of the PSD. This limitation is simply a result of the light scattering patterns and it is expected theoretically. More specifically, it stems from the fact that for some combinations of optical properties and particle size, a light scattering function (the wavelength exponent) changes very slowly with the relative size of the particles to the wavelength. When this happens, in the presence of experimental noise, estimation of the full PSD is not possible. In some cases this limitation can be overcome by simply altering the optical properties of the suspension (i.e. choosing proper wavelengths for the turbidity measurements or a medium different than water to suspend the particles). Therefore, to make the best use of the method and interpret the results in a meaningful way, one should be aware of the regimes where this limitation occurs.

Because of the behavior of the wavelength exponent, turbidimetric techniques that utilize the measurement of the particle volume fraction (which is a measurement of

the particle size and number independent of the scattering properties) provide reliable estimates for the particle size (the PSD or an average diameter) in a wider range of sizes and optical properties than techniques that utilize turbidity measurements only.

In this article, a brief overview of light scattering theory is first presented followed by a description of the turbidimetric techniques that are most commonly used for particle size determination. For each technique we include its theoretical background, comments on its advantages and limitations and references to its successful applications in the literature. We also include discussions regarding the regions of particle sizes and optical properties where the technique may present difficulties in providing reliable estimates of the particle size or the PSD. We then present cases where turbidimetry was used to provide estimates of the average diameters of the PSD and discuss the advantages and pitfalls of such uses. We follow with details on the procedure such as choice of wavelengths, calculation of refractive index and instrumentation. The sensitivity of the turbidimetric methods to experimental error is extensively discussed. Applications on the use of the method for on-line particle size measurements follow. We conclude with a discussion on how users should proceed with choosing the appropriate method for their application and with comparing results from other particle sizing techniques. Throughout the article several applications reported in the literature are critically discussed in order to point out some approaches with serious limitations and some coincidental observations that may result in misleading conclusions. In this way the readers can judge if the approaches reported in the literature are suitable for their use.

2 THEORETICAL BACKGROUND

2.1 Turbidity and Particle Size

Turbidity, \( \tau_{\lambda_0} \) (cm\(^{-1}\)), gives a measure of the attenuation of the intensity of a beam of light traversing through a suspension of particles (Equation 1):

\[
\tau_{\lambda_0} = \frac{1}{l} \ln \left( \frac{I_0}{I} \right)
\]

where \( I_0 \) and \( I \) represent intensities of the incident and transmitted beams, respectively, and \( l \) is the length of the optical path (i.e. cell length, cm). The value of the turbidity changes with the wavelength of the incident light beam, \( \lambda_0 \). \( I \) is measured at 180° to \( I_0 \).

The attenuation of the intensity of light traversing through a particle suspension is due to scattering of light by the particles and in some cases (depending on the wavelength) absorption of light by the particles and/or the medium. The amount of light scattered and absorbed by the particles depends on their size, their concentration in the suspension, the size of the particles relative to the wavelength of the incident beam and the refractive indices of the particles and the medium. Therefore, theoretically, turbidity can be related to the particle size. For a monodisperse suspension (particles of equal diameter, \( D \)) of spherical, isotropic particles, in the absence of multiple scattering (Equation 2):

\[
\tau_{\lambda_0} = N \frac{\pi D^2}{4} K_{ext}
\]

where \( N \) is the number of particles per cm\(^3\) and \( K_{ext} \) is the extinction coefficient at wavelength \( \lambda_0 \). \( K_{ext} \) is equal to the sum of the absorption \( K_{abs} \) and the scattering \( K_{scat} \) coefficients. The extinction coefficient can be calculated from the rigorous Mie theory and the equations for this calculation can be found in several sources.\(^{3,33–36}\) In the work presented in this article we assume no absorption (\( K_{ext} = K_{scat} \)) and this is the case for most of the work reported in the literature. In most of the reported applications workers have chosen to avoid wavelengths where the medium or the particles absorb, for practical reasons, explained in section 6.3. However, should readers decide to work with absorbing particles, they should use \( K_{ext} \) for Equations (3), (4), (12), (13), (15) and (18). The validity of the discussions in this article does not change with the nonabsorption assumption.

For a monodisperse suspension of spherical, nonabsorbing, isotropic particles, in the absence of multiple scattering (Equation 3):

\[
\tau_{\lambda_0} = NR_{scat} = N \frac{\pi D^2}{4} K_{scat} = N \frac{\pi D^2}{4} K \left( \frac{D}{\lambda_m}, \frac{n_p}{n_m} \right)
\]

where \( R_{scat} \), the scattering cross-section, is the total energy scattered by one sphere when the incident light is of unit intensity and either plane polarized or unpolarized. The scattering coefficient, \( K_{scat} \), or \( K(D/\lambda_m, n_p/n_m) \), is dimensionless and it is an involved function of two parameters, \( \alpha \) and \( m \). \( \alpha = \pi(D/\lambda_m) \) is defined as the relative size of the particle diameter to the wavelength of the light in the medium (\( \lambda_m \)) and \( m = n_p/n_m \) is the ratio of the refractive index of the particles to the refractive index of the medium. \( \lambda_m = \lambda_0/n_m \), where \( \lambda_0 \) is the wavelength of the incident beam in vacuo. Both \( n_p \) and \( n_m \) are evaluated at \( \lambda_0 \). The estimation of the refractive indices for homogeneous and inhomogeneous particles is discussed in section 6.2. In cases where the particles absorb, the refractive index has both real and imaginary parts.

For a polydispers suspension of spherical nonabsorbing, isotropic particles, in the absence of multiple
scattering turbidity is given by Equation (4):

$$\tau_{\alpha} = N \int_0^{\infty} \frac{\pi D^2}{4} K \left( \frac{D}{\lambda_m} \frac{n_p}{n_m} \right) f(D) \, d(D)$$

(4)

where $f(D)$ is the normalized PSD.

In general, because $K_{\text{scat}}$ is an involved nonlinear function of $\alpha$ (i.e. $D/\lambda_m$), it is possible from turbidity measurements at a sufficient number of wavelengths (or a combination of turbidity measurements and other properties of the particle suspension) to estimate the size of the particles in a monodisperse suspension or the PSD in a polydisperse suspension. However, it has been shown$^{[33]}$ that for certain combinations of $(m, \alpha)$ values the estimation of the particle size or the PSD of the suspension may present difficulties with some turbidimetric techniques. Being aware of these $(m, \alpha)$ regimes will help the user choose the proper turbidimetric technique and proper wavelengths to work with in order to obtain the most reliable estimate of particle size of a suspension.

### 2.2 The Scattering Coefficient

Certain features in the behavior of the scattering coefficient are important in explaining the capability of turbidimetric techniques to provide the particle size or the PSD of a suspension. These features will be discussed here in some detail. The scattering coefficient is defined as the ratio of the scattering to the geometrical cross-section. The scattering coefficient exhibits an oscillatory dependence on $\alpha$, with a series of successive minima and maxima (Figure 1). The first maximum occurs at lower $\alpha$ values the larger is the value of $m$; the numerical value of $K_{\text{scat}}$ at the first maximum is larger the larger is $m$. At large values of $\alpha$, $m$ has virtually no effect on $K_{\text{scat}}$, in agreement with the theory of diffraction for objects very large compared with the wavelength used, and $K_{\text{scat}}$ approaches the value of 2. Values of $K_{\text{scat}}$ for various large $\alpha$ values are shown in Table 2. Note that for $m = 1.2$ and 200 $< \alpha < 220$ the value of the oscillating $K_{\text{scat}}$ can be found between 2.12 and 1.99, whereas for 2500 $< \alpha < 2700$, $K_{\text{scat}}$ oscillates between 2.016 and 2.006. When plotted against $\alpha$, the scattering coefficient also exhibits secondary fluctuations (ripples) that become increasingly irregular for higher values of $m$. Another parameter which is often used in light scattering is $\rho = 2\alpha(m - 1)$; $\rho$ is the phase shift suffered by a wave passing through the center of a sphere.$^{[37]}$ When $K_{\text{scat}}$ is plotted against $\rho$, the $\rho$ position of the extremes (minima and maxima) of the main oscillation is independent of the value of $m$.$^{[33,34]}$ Recall that this discussion is for spherical, isotropic spheres. Scattering for nonspherical particles is an area of active research$^{[38]}$ and publications are available.$^{[39–41]}$

As mentioned earlier, in the general case the scattering coefficient can be calculated from the rigorous Mie theory.$^{[33–36]}$ In certain $(m, \alpha)$ regimes the equations for $K_{\text{scat}}$ can be approximated with simple expressions which give $K_{\text{scat}}$ within 1% accuracy from its true value.$^{[37]}$ These expressions are discussed here because they help in elucidating some of the problems encountered by researchers when converting turbidity measurements to particle size.

1. When the suspended particles are very small compared with the wavelength both outside ($\alpha \ll 1$) and inside ($|in\alpha| \ll 1$), the particle$^{[34,37,42]}$ the Rayleigh scattering theory gives Equation (5):

$$K \left( \frac{D}{\lambda_m} \frac{n_p}{n_m} \right) = \frac{8}{3} \left( \frac{m^2 - 1}{m^2 + 2} \right)^2 \alpha^4$$

(5)

2. For particles very large compared with the wavelength, the scattering coefficient approaches a

constant value independent of \( m \) (Equation 6):

\[
K \left( \frac{D}{\lambda_m}, \frac{n_p}{n_m} \right) = 2
\]  

(Walstra\(^{37} \) has reported that this is true for \( \rho = 2 \alpha(m-1) > 300 \) and \( \alpha > 2000 \). Table 2 gives the range of \( K_{\text{scat}} \) values for different \( \alpha \) values and \( m = 1.1 \) and 1.2. Note that for \( m = 1.2 \) and \( \alpha \) values between 200 and 220 the values of the oscillating \( K_{\text{scat}} \) can be found between 2.12 and 1.99. Assuming a constant value of 2.0 may introduce a maximum of 6% error in \( K_{\text{scat}} \) in this range. For very large values of \( \alpha \), assuming \( K_{\text{scat}} = 2.0 \) gives \( K_{\text{scat}} \) within 1% accuracy from the true value.)

Equations (5) and (6) are the two extremes of a general expression where for monodisperse suspensions of nonabsorbing spheres, the dependence of the scattering coefficient on the diameter at a given wavelength is approximated by Equation (7):\(^{4,5} \)

\[
K \left( \frac{D}{\lambda_m}, \frac{n_p}{n_m} \right) = k' \left( \frac{D}{\lambda_m} \right)^z = k' \lambda_m^z
\]  

where \( k' \) and \( k'_c \) are proportionality constants. Note that \( z = 4 \) in the Rayleigh regime and \( z = 0 \) for large particles (compare Equation 7 with Equations 5 and 6, respectively). When plotting \( K_{\text{scat}} \) against the wavelength for constant \( D \), we have \( K_{\text{scat}} = k'' \lambda_m^{-z} \), and therefore \( z \) has been termed “the wavelength exponent”.\(^{43} \) When plotting \( K_{\text{scat}} \) against \( \alpha \) at constant \( \lambda_m \), we can write Equation (8):

\[
\ln(K_{\text{scat}}) = z \ln \alpha + \ln k'_c
\]  

The value of \( z \) can be obtained for any \( \alpha \) at any \( m \) value from the slope of \( \ln K_{\text{scat}} \) vs \( \ln \alpha \).

2.3 Turbidity and Moments of the Particle Size Distribution

In regimes where \( K_{\text{scat}} \) can be approximated by Equation (7), the turbidity of a monodisperse suspension at a given wavelength \( \lambda_0 \) can be written as \( \tau = N_k D^y \), where \( y = z + 2 \) and \( k \) is a constant. Several authors\(^{5,43} \) have tabulated values of \( y \) or \( z \) for several pairs of \( (m, \alpha) \) values (in the notation of Heller et al.,\(^{43} \) \( z \approx n \)). Values of \( y \) and \( z \) are plotted in Figure 2 for several \( m \) values and \( \alpha < 12.0 \). From Equations (4) and (7), for a polydisperse system, at a given \( \lambda_0 \), we can write Equation (9):

\[
\tau_{\lambda_0} = N_k \int_0^\infty k(D) D^y f(D) d(D)
\]  

\[\text{where both } k \text{ and } y \text{ are functions of } D. \text{ When the particle sizes in the suspension are such that } k \text{ and } y \text{ do not change significantly with } D, \text{ then (Equation 10):}

\[
\tau_{\lambda_0} = N_k \int_0^\infty D^y f(D) d(D) = Nk J_y
\]  

where \( k \) and \( y \) are constants. In these cases, turbidity is proportional to the yth moment, \( J_y \), of the PSD. The value of \( y \) (i.e. the order of the moment) changes with \( \alpha \) and \( m \) (Figure 2). For \( \alpha < 0.5 \), \( y \) approaches the limiting value of 6 (\( z = 4 \), Rayleigh regime) and therefore turbidity is proportional to the sixth moment of the PSD. For values of \( m \) between 1.1 and 1.2, and for \( \alpha < 1.6 \), the value of \( y \) is almost independent of the value of \( m \). Kourt et al.\(^{15,32,44} \) discussed that for small values of \( m \) (\( m = 1.05, 1.1, 1.15 \)) the value of \( y \) is approximately 4.0 (4.2 \( \leq y \leq 3.8 \)) for a very wide range of \( \alpha \) values (for \( m = 1.05 \), \( 3 < \alpha < 14 \); for \( m = 1.15 \), \( 3 < \alpha < 6 \)). For suspensions with PSDs in the above \( (m, \alpha) \) regions, turbidity would be approximately proportional to the fourth moment of the PSD. Finally, for very large particles, \( y = 2 \) and turbidity is proportional to the second moment of the PSD.

3 PARTICLE SIZE DETERMINATION IN MONODISPERSE SUSPENSIONS

The turbidity of a suspension of spherical particles as given in Equation (3) is a function of both the number concentration of particles \( N \) and the particle diameter \( D \). The estimation of these two unknowns requires sufficient measurements of turbidity at different wavelengths or measurements of turbidity and another property that is also related to particle concentration and diameter. Two approaches have been used in the literature:\(^{33} \) the turbidity at a given wavelength is divided
either by the particle volume fraction or by the turbidity value at another wavelength, such that the unknown number of particles is eliminated, and the new quantity is related to particle size only. Once the particle size is determined, substitution into Equation (3) will give $N$.

### 3.1 Specific Turbidity

The volume fraction of the spherical particles in a monodisperse suspension is given by Equation (11):

$$\phi = \frac{N \pi D^3}{6}$$

The particle volume fraction can be measured (see section 6.5) using gravimetric analysis or densitometry.\(^{(21,23,45)}\) The specific turbidity, defined as the ratio of the turbidity of the suspension to the volume fraction of the suspended particles, is independent of the particle number concentration (Equation 12):

$$\tau_{\lambda} = \frac{3 K}{2} \frac{D}{\phi} \frac{n_p}{n_m}$$

Specific turbidity is plotted against diameter in Figure 3 for two different types of particles suspended in water: poly(vinyl acetate) with $m \approx 1.1$ and polystyrene with $m \approx 1.2$. The particle diameter $D$ can be calculated from one turbidity measurement and the particle volume fraction when the optical properties of the suspension are known and the expected particle size range is known. For example, if it is known that we have submicrometer particles then one specific turbidity measurement for poly(vinyl acetate) at 600 or 400 nm would give the particle diameter. Note that owing to the oscillatory behavior of the specific turbidity, more diameters may correspond to one specific turbidity value. For example, for polystyrene a specific turbidity reading of 15 000 cm\(^{-1}\) at 400 nm in the range shown in Figure 3 corresponds to six different diameters ($0.15, 1.7075, 1.855, 1.865, 1.9225$ and 2.56$\mu$m; four due to the main oscillating pattern of $K_{\text{scat}}$ and two due to a secondary rippling effect). Therefore, if the size range is not a priori known, measurements at two (preferably widely spaced) wavelengths are required to extend the applicability of the method to a wide range of particle sizes.\(^{(15)}\)

### 3.2 Turbidity Ratio

The ratio of two turbidity readings taken at two wavelengths is a quantity independent of the particle number concentration (Equation 13):

$$\frac{\tau_{\lambda_{01}}}{\tau_{\lambda_{02}}} = \frac{K}{D} \frac{D}{\phi} \frac{n_p}{n_m} \frac{\lambda_{01}}{\lambda_{02}}$$

Subscripts $\lambda_{01}$ and $\lambda_{02}$ denote that the quantities $\tau$, $n_p$, $n_m$ and $\lambda_m$ are evaluated at these wavelengths; $\lambda_{01}$, $\lambda_{02}$ are the wavelengths in vacuo. Figure 4(a) shows the turbidity ratio (at 400/600 nm) for polystyrene and poly(vinyl acetate) particles suspended in water. The particle diameter could be estimated from one turbidity ratio (two turbidity measurements) if the ratio was a monotonic function of particle size or $\alpha$. However, this is not the case, as can be seen in Figure 4(a). An indentation exists in the turbidity ratio vs $\alpha$ curve, at the lower $\alpha$ regime, owing to the first inflection point of the $K_{\text{scat}}$ vs $\alpha$ curve (in polydisperse suspensions, this indentation vanishes). Also, for larger particles, the turbidity ratio vs $\alpha$ curve exhibits an oscillatory behavior. Therefore, unless the size range is a priori known, a reading at a third wavelength (two turbidity ratios) is advised, to define uniquely the particle size. Again once the particle size is estimated the number of particles can be calculated from Equation (3).

An example where only one turbidity ratio is not sufficient to determine the particle size was reported by Kourti.\(^{(15)}\) The turbidity ratio measurement at $\lambda_{01} = 400$ nm and $\lambda_{02} = 500$ nm for a 60:40 poly(styrene–butadiene) latex was repeated several times.
TURBIDIMETRY IN PARTICLE SIZE ANALYSIS

Figure 4 (a) Turbidity ratio at 400/600 nm plotted against particle diameter for polystyrene with \( m \approx 1.2 \) and poly(vinyl acetate) with \( m \approx 1.1 \) latexes. (b) Turbidity ratios for polystyrene, \( m \approx 1.2 \). Note that owing to the oscillation in the curves, particle suspensions with two different diameters (0.2 and 0.25 \( \mu \)m) give the same turbidity ratio values at two different wavelengths.

(For four different dilutions of the same sample). Each time, two estimates (two solutions) of particle size were obtained. In one of the solutions the estimates of the diameter were between 209 and 228 nm and in the other between 157 and 165 nm. Results from other methods had shown that the true diameter range was around 200 nm [specific turbidity (208–221 nm), HDC (228 nm) and DLS (194 nm)] and therefore the first solution could be picked as the correct one. Caution should be exercised when diameters are in a range around the first indentation in the turbidity ratio–diameter curve when using the turbidity ratio method. Figure 4(b) shows turbidity ratios (\( \tau_{400}/\tau_{600} \) and \( \tau_{500}/\tau_{600} \)) plotted against diameter for monodisperse polystyrene suspensions. The diameters are in a range around the first indentation in the turbidity ratio–diameter curve. Note that suspensions with two very different particle sizes (0.2 and 0.25 \( \mu \)m) will give the same turbidity ratio at two different wavelengths (1.72 for \( \tau_{500}/\tau_{600} \) and 3.54 for \( \tau_{400}/\tau_{600} \)). In fact, for this example, with an experimental error as small as 2.0% in the turbidity ratios, any solution between 0.2 and 0.25 \( \mu \)m is possible. It would be preferable if the three wavelengths at which the measurements were taken were more widely separated.

The turbidity ratio method practically gives no information on the particle size for (i) very large particles, where for all the wavelengths used the scattering coefficient is constant (substitution of \( K_{\text{scat}} = 2 \) in Equation 13 gives a turbidity ratio equal to unity), and (ii) very small particles, where for all the wavelengths used the Rayleigh Equation (5) applies and turbidity ratio becomes independent of the particle size.

4 PARTICLE SIZE DISTRIBUTION DETERMINATION IN POLYDISPERSE SUSPENSIONS

Specific turbidity and turbidity ratio measurements can also be used to estimate the PSD in polydisperse suspensions. Numerical approaches that can be used to solve for the PSD from turbidity and specific turbidity measurements are discussed in detail in section 4.5. However, the estimation of the full PSD is not always possible with turbidimetry. Some turbidimetric techniques are not theoretically expected to provide the full PSD of a suspension if, because of its optical properties (refractive indices of medium and particles) and the sizes of the particles, the \((m, a)\) values of the suspension are within certain ranges. In such cases the specific turbidity technique will provide an estimate of an average diameter while techniques similar to the turbidity ratio provide no information on the particle size. The \((m, a)\) regimes where the estimation of the full PSD is practically possible are discussed for each one of the turbidimetric methods presented in this section.

4.1 Specific Turbidity

Examples of successful applications of the method for particle and droplet size distribution determination can be found in Meehan and Beattie, Walstra and Yang and Hogg. For a polydisperse suspension of spherical particles, the volume fraction is (Equation 14):

\[
\phi = N \int_0^\infty \frac{\pi D^3}{6} f(D) \, d(D) = N \frac{\pi}{6} J_3
\]
where $J_3$ is the third moment of the PSD. The specific turbidity is given by Equation (15a):

$$\frac{\tau_{ha}}{\phi} = \frac{3}{2} \int_0^\infty \frac{D^2K}{D_m} \frac{D}{n_m} \frac{m}{m} f(D) d(D)$$

(15a)

Alternatively, the specific turbidity of a suspension can be written as Equation (15b):

$$\frac{\tau_{ha}}{\phi} = \frac{3}{\phi} \int_0^\infty \frac{\tau(D, \lambda_0) F(D) d(D)}{\phi}$$

(15b)

where $\tau/\phi(D, \lambda_0)$ is the specific turbidity corresponding to particles with diameter $D$ and wavelength $\lambda_0$ and $F(D)$ is the normalized PSD on a weight basis.

For a suspension of spheres, when the optical properties of the suspension are known, a minimum of $P$ specific turbidity measurements are required for the estimation of a $P$ parameter PSD from Equation (15a) or (15b), as discussed in the next section. For example, if we assume that the PSD is known to be log-normal described by the mean diameter and the variance, we need at least two specific turbidity measurements. If the form of the PSD is not assumed and we attempt to recover the frequency distribution at $P$ given diameters (i.e. $P$ discrete points), then at least $P$ specific turbidity measurements are required.

In the presence of experimental error, the estimation of the full PSD from Equation (15a) or (15b) is impossible if all the turbidities (i.e. at all the wavelengths required for the estimation) are approximately proportional to the same moment of the PSD, $J_3$. Given that $\phi$ is always proportional to the third moment $J_3$ of the PSD, in these cases specific turbidity becomes proportional to $J_3/D_3$, that is proportional to the $(y - 3)rd$ power of the $D_{a3}$ average diameter.\(^{(32)}\) Kourti et al.\(^{(32)}\) showed that when this happens for all of the $P$ wavelengths used, many alternative solutions (PSDs) correspond to the same specific turbidity measurements and it is impossible to isolate the true solution unless there is some a priori knowledge. However, all these alternative solutions have their $D_{a3}$ average diameters numerically very close to each other. In that case it was suggested that only this average diameter $D_{a3}$ can be correctly estimated from specific turbidities\(^{(15, 32)}\) in this range of wavelengths. The $(m, a)$ regimes where the full PSD is practically impossible to estimate for nonabsorbing particles are as follows:

1. For any $m$ value and very small $a$ (Rayleigh regime). If for all the wavelengths used for the turbidity measurements we are in the Rayleigh regime, then substitution of Equation (5) in Equation (15a) gives Equation (16):

$$\frac{\tau_{ha}}{\phi} = k_{ha} \int_0^\infty \frac{D^2f(D) d(D)}{D^3 \int_0^\infty f(D) d(D)} = k_{ha} \frac{J_0}{J_3} = k_{ha} D_3$$

(16)

where $D_3$ is the turbidity-average diameter and $k_{ha} = \frac{4\pi^4}{m^2} \frac{a}{m^2 + 2}$ and the subscript $\lambda_0$ denotes that $\tau$, $\lambda_m$ and $m$ are evaluated at $\lambda_0$. Llosent et al.\(^{(32)}\) tried to estimate the full PSD in the Rayleigh regime using either an assumed shape of the PSD or using a regularization method (discussed later) to solve at discrete points for the PSD. Their results confirmed the suggestions of Kourti et al.\(^{(32)}\) that only the turbidity-average diameter can be correctly estimated in these regimes.

2. For any $m$ value and very large diameters (where $K_{scat} \approx 2$), we have Equation (17):

$$\frac{\tau_{ha}}{\phi} = \frac{3}{\phi} \int_0^\infty \frac{D^2f(D) d(D)}{D^3 \int_0^\infty f(D) d(D)} = \frac{3}{D_{32}}$$

(17)

$D_{32}$, the volume–surface average, is also sometimes referred to as the Sauter mean diameter.

3. $(m, a)$ regimes where the exponent $y$ is close to 4.0. In an extensive study with theoretical analysis and experimental validation, Kourti et al.\(^{(15, 32)}\) showed that for suspensions with PSDs in $(m, a)$ regimes where the exponent $y$ is very close to 4.0 ($3.8 < y < 4.2$), specific turbidities result in apparent diameters numerically very close to the weight average ($D_{a3}$ or $D_{a3}$) of the true PSD. The regimes of $(m, a)$ values where this happens can be read from a $y$ vs $a$ plot, such as that in Figure 2. From such a plot we can see that $a \approx 4$, for $m = 1.05$ at $3.0 < a < 14$ and for $m = 1.15$ at $3.0 < a < 6.0$. If the whole distribution covers $a$ values in this regime for all the wavelengths used for the turbidity measurements, then within experimental error many alternative solutions are possible and only the weight-average of the distribution can be correctly estimated. This is true for any type of distribution (multimodal or unimodal continuous distribution, or simply the mixture of two populations). Table 3 gives an illustration of the effect of small measurement errors on the estimation of the PSD in these regimes, for $m = 1.1$. In case A, the true distribution is log-normal (see Equation 21) with $D_g = 175$ nm and $\sigma = 0.2$ and weight-average diameter $D_{a3} = 201$ nm. The turbidities for such a suspension were theoretically calculated at three
wavelengths. An error of less than 1.0% was then introduced in the three turbidity values and the parameters of the PSD were re-estimated (case A1). Note that the estimated $D_w = 199$ is within 1% of the value of the true weight average of the PSD whereas $D_g$ and $\sigma$ are significantly different. A different random error less than 1% was introduced in the three turbidities for case A2. Again, only the weight average of the estimated distribution $D_w = 202$ is within 0.5% of the true value and the other parameters are significantly different from the true distribution but also from case A1. Similar results were obtained for case B. For different random errors of ±1.2% on the turbidity values, cases B1 and B2 were obtained with weight averages within 2% of the true value but with all the other parameters significantly different from the true distribution.

Reports in the literature confirm that the PSD cannot be estimated with specific turbidity in some cases. Haseler(19) working with Ektacolor suspensions ($m = 1.15$) reported that experimental errors in specific turbidities (measured at 400 and 700 nm) would lead to large errors in the calculated distribution. These results were observed because of the small $(m, \sigma)$ values with which he was working. Based on the above discussion, only $D_w$ could be correctly estimated in those $(m, \sigma)$ regimes. Walstra, (16) trying to estimate the globule size distribution in cow’s milk $(m = 1.1)$ from specific turbidity measurements, reported that for very fine emulsions ($D_{1,2} < 200$ nm) with rather high polydispersity the reliability of the method decreases and showed that a set of experimental data could be fitted to many different types of distributions with the same $D_w$.

The observations of Kourti et al. (15,32) revealed a very useful property of the specific turbidity: the weight-average diameter of suspensions can be correctly estimated even though the determination of the PSD is impossible. This property of specific turbidity can be utilized for practical purposes where a fast estimate of the weight-average diameter is required and is sufficient to monitor the progress of a process. Gossen (23, 24, 46) utilized this information and used specific turbidity to monitor the progress of polymerization reactions with on-line measurements. The $\sigma$ range where specific turbidity measurements give $D_w$ may be extended further when the distribution is log-normal. For example, for suspensions with $m = 1.1$ and log-normal distributions of submicrometer particles, it has been observed that the mean value of the apparent diameters, estimated from specific turbidities at 400 and 600 nm, is within 5% the true weight average diameter of the PSD. (15, 32) Monitoring these two apparent diameters gives information on the weight average of the PSD.

It should be noted that in all the regimes where the estimation of the full PSD is impossible, specific turbidity gives good estimates of meaningful average diameters. Compared with other turbidimetric techniques, where information only from turbidity measurements is used, the specific turbidity has the advantage that an additional measurement is used, the solids volume fraction, which is always proportional to the third moment of the PSD. Therefore, whenever turbidities at two or more wavelengths are proportional to the $n$th moment of the distribution, although the estimation of the true PSD is impossible, a meaningful average of the PSD, the $D_{1,3}$ average, can always be obtained from specific turbidity measurements.

### 4.2 Turbidity Ratio

The ratio of two turbidity readings taken at different wavelengths for a polydisperse suspension is given by Equation (18):

$$\frac{\tau_{\lambda_{01}}}{\tau_{\lambda_{02}}} = \frac{\int_0^\infty D^2 K \frac{d}{dx} \frac{n_p}{n_m} \lambda_{01} f(D) \, dD}{\int_0^\infty D^2 K \frac{d}{dx} \frac{n_p}{n_m} \lambda_{02} f(D) \, dD}$$

Again, subscripts $\lambda_{01}$ and $\lambda_{02}$ denote that the quantities $\tau$, $n_p$, $n_m$ and $\lambda_m$ are evaluated at the corresponding wavelengths; $\lambda_{01}$, $\lambda_{02}$ are wavelengths in vacuo. For a PSD described by $P$ parameters, a minimum of $(P + 1)$ turbidity measurements at different wavelengths (one of
which is chosen as reference) are required, in principle, for the estimation of these parameters. The method gives no information on the particle size in the following cases, for nonabsorbing particles:

1. For any value of \( m \) and very large particles where \( K_{\text{scat}} = 2 \), the turbidity ratio equals 1.0.

2. For any value of \( m \) and very small particles, where the Rayleigh Equation (5) applies, the turbidity ratio equals a constant value, independent of the particle size.

3. When, for all the wavelengths used, turbidities are approximately proportional to the same moment of the PSD. This case is observed for very small \( m \) values (\( m \approx 1.15, 1.1, 1.05 \)) and for a very wide range of \( \alpha \) values below the first \( K_{\text{scat}} \) maximum, where the exponent \( y \) changes very slowly with \( \alpha \). This in turn means that even for broad distributions with sizes falling in these \( \alpha \) regimes, turbidities at widely separated wavelengths will be proportional to approximately the same moment of the PSD, and their ratio will be almost independent of the particle size. Kourti et al.\(^{15,32} \) showed that for \( m = 1 \) and submicrometer particles, the estimation of the true PSD from turbidity measurements at 350 and 700 nm (with reference \( \lambda_0 = 546 \text{ nm} \)) is impossible for measurement errors as small as 0.5%. One example is reported in which the effect of error on the estimated PSD is studied for a turbidity ratio error as small as \( \pm 0.35\% \) in the above three wavelengths. The PSD was re-estimated for different errors (less than \( \pm 0.35\% \)) each time. Several very different log-normal distributions were obtained; for example, one of the estimated PSDs had a geometric mean \( D_g = 500 \text{ nm} \) and standard deviation \( \sigma = 0.15 \), \( D_w = 541 \text{ nm} \) and polydispersity 1.05, while another had \( D_g = 285 \text{ nm} \), \( \sigma = 0.4 \), \( D_w = 499 \text{ nm} \) and polydispersity 1.6.

The turbidity ratio method should therefore be avoided for the estimation of the PSD for systems of very small or very large particles and for systems with small \( m \) values (\( m < 1.15 \)) and \( \alpha \) values below approximately 10 (for a short wavelength of 400 nm and water medium, these \( \alpha \) values cover all the submicrometer size range). In these regimes the method is so sensitive to experimental error that it offers practically no information on the size of the suspended particles (i.e., neither the PSD nor an average can be estimated).

Owing to the behavior of the turbidity ratio in the ranges of \( (m, \alpha) \) values described above, controversial reports on the capabilities of the turbidity ratio to provide the full PSD have appeared in the literature. Wallach and Heller\(^7 \) obtained estimates very close to the true distribution for polystyrene suspensions (\( m = 1.2 \)) with particle diameters between 650 nm and 1.3 \( \mu \text{m} \) from turbidity measurements at \( \lambda_{01} = 440 \text{ nm}, \lambda_{02} = 610 \text{ nm} \) and \( \lambda_{03} = 546 \text{ nm} \). The values of \( m \) and \( \alpha \) in their system were such as to allow for successful PSD determination. However, when Haseler\(^19 \) tried the turbidity ratio method for a system with smaller \( m \) and \( \alpha \) values (\( m = 1.15, \lambda_0 \) in the range 400–700 nm and submicrometer particles), he reported that within experimental error a large number of different distributions gave the same turbidity spectra. Similarly, Maxim et al.\(^{31} \) reported that the “turbidity ratio leads to multivalued solutions and unless prior estimates of the answer by some other method are available there are no criteria for choosing between alternative solutions”. They were working with small \( m \) values (\( m = 1.1 \)), submicrometer particles and wavelengths of 320–720 nm with a reference wavelength of 546 nm, that is an \( (m, \alpha) \) area where Kourti\(^{15} \) showed that even a 0.5% error in the turbidity ratio measurements means that the PSD estimation is practically impossible. The results of both Haseler and Maxim et al. were expected based on the \( (m, \alpha) \) values of their systems. It is clear from the above examples that one cannot generalize conclusions on the capability of turbidimetric techniques to provide the PSD across \( (m, \alpha) \) values.

4.2.1 Methods Similar to Turbidity Ratio

Alternatively to Equation (18), some authors\(^{47,48} \) use the ratio given in Equation (19):

\[
\frac{(\tau \lambda/\phi)_{\lambda_{01}}}{(\tau \lambda/\phi)_{\lambda_{02}}} \quad (19)
\]

Notice that, numerically, \( \phi \) is eliminated from Equation (19), hence there is no reason to measure it. Other authors use the \( DQ \) (dispersion-quotient) method (Equation 20):\(^{33} \)

\[
DQ = \frac{\tau_{\lambda_{02}} \lambda_{02}^2}{\tau_{\lambda_{01}} \lambda_{01}^2} \quad (20)
\]

Both of the above approaches have the same limitations as the turbidity ratio method for the estimation of the PSD.

4.3 The Wavelength Exponent Technique

In this approach, the particle size can be estimated only from turbidity measurements as in the turbidity ratio technique (i.e., the particle volume fraction does not need to be known). The change of the turbidity of a suspension with the wavelength is recorded and related to the size of the suspended particles. The technique is described in detail in Bateman et al.\(^{49} \), Heller et al.\(^{43} \) and Kourti.\(^{15} \)

It has been shown\(^{15,50} \) that the turbidity ratio and the wavelength exponent are theoretically equivalent.
methods for the determination of the parameters of the PSD. The functions used in the formulations of the two techniques to convert the turbidity measurements to PSDs can be derived from each other, and in case of no measurement error the use of either method gives identical results. Consequently, in the \((m, a)\) regions where the estimation of the particle size in a suspension is not possible using the turbidity ratio method, the wavelength exponent method also fails. It should also be noted that although the two methods are theoretically equivalent for the determination of the PSD, the formulation of the turbidity ratio method is less complex than that of the wavelength exponent. Consequently, the turbidity ratio method requires less computation to calculate the PSD and the error propagation is smaller.

Melik and Fogler\(^{48}\) suggested an approach in which a combination of the wavelength exponent and the turbidity ratio method is used and claimed that with this approach the two parameters of the PSD can be estimated from only two turbidity measurements. However, since these are not two different methods but are theoretically equivalent, at least three turbidity measurements are required for the determination of a two-parameter PSD using either of the methods or their combination. Otherwise (i.e. using two turbidity measurements only), an infinite number of solutions will be obtained. The claims of Melik and Fogler\(^{48}\) were shown\(^{50}\) to be unfounded.

### 4.4 Resolution of a Conflict in the Literature

The analysis presented by Kourti et al.\(^{15,32}\) which showed that the capability of a turbidimetric technique to provide the PSD is strongly related to the \((m, a)\) values of the suspension helped to resolve a controversy that existed in the literature. This conflict, on whether the true PSD of a suspension can be estimated from turbidimetric techniques, arose between Maxim et al.\(^{31}\) and Zollars.\(^{11,12}\) As discussed earlier, Maxim et al. used the turbidity ratio method to estimate the full PSD in commercial suspensions, with \(m = 1.1\) and particles with diameters smaller than 1.0 µm. A high correlation between the parameters of the distribution was observed. The authors stated that a valid estimate of the true distribution is impossible in the presence of experimental error. According to the analysis presented by Kourti et al.\(^{52}\) these observations are justified (and were expected) for the \((m, a)\) values of the suspension and the turbidity ratio method. Zollars used a simulation study with no experimental error to re-estimate the parameters of log-normal PSDs from theoretically calculated specific turbidities. Of course, the parameters were correctly re-estimated. The author stated that “turbidimetry does not exhibit multiple solutions as reported by other investigators”. His observations\(^{11,12}\) are also justified for a specific turbidity method and re-estimation of the parameters with no experimental error. Both the workers were correct for the types of cases they were studying. However, their findings cannot be extrapolated over turbidimetric methods and \((m, a)\) regimes. This extrapolation caused the controversy.

### 4.5 Solving for the Particle Size Distribution

Equations (15a) and (18) give the value of the specific turbidity or turbidity ratio, respectively, at given wavelengths if the PSD, \(f(D)\), is known. The inverse problem is to determine the PSD given the turbidity or the specific turbidity measurements at several wavelengths, \(\lambda_0\). If a continuous set of measurements of \(\tau_{\lambda_0}\) vs \(\lambda_0\) was available, one could theoretically deconvolute these equations to yield \(f(D)\). However, in practice, one usually has turbidity measurements at a finite number of wavelengths, so we have to reconstruct \(f(D)\) from only a number of discrete values of \(\tau_{\lambda_0}\). This is a typical problem in science.\(^{51}\) We routinely measure “enough points” and then “draw a curve through them”. In doing so for this problem, we are making some assumptions either about the underlying function \(f(D)\) or about the nature of \(K_{\text{scat}}\), or both.

Two approaches have been taken in the literature to solve for \(f(D)\). When a small number of turbidity measurements are available, a type of distribution that can be described by a few parameters is assumed for \(f(D)\) (i.e. Gaussian, log-normal, etc.) and we solve for these parameters. When many turbidity measurements are available it is possible in some cases to solve for \(f_i\) [the discretized \(f(D)\)] at a number of selected diameters, \(D_i\). In general, the second approach requires many more turbidity measurements than the first.

#### 4.5.1 Approximate the Particle Size Distribution with a Known Distributional Form

When a small number of turbidity measurements are available, a convenient approach is to approximate \(f(D)\) with a distributional form that can be described by a few parameters. This form is then substituted into Equation (15a) or (18) and its parameters are estimated from the turbidity measurements using non-linear parameter estimation procedures such as the Levenberg–Marquardt algorithm.\(^{52}\) The assumed distributional form is one that is known to describe similar systems (e.g. for latex particles the log-normal distribution described by two parameters is frequently used).

Extensive reviews on the distributional forms that have been used to describe the PSD in various suspensions can be found in several sources.\(^{15,33,53}\) Some workers\(^{1}\) calculated turbidity for a Gaussian distribution of spheres. However, most naturally occurring
populations are skewed and not symmetrical. The logarithmic normal distribution\(^{11,15,20,33}\) has been used to described such populations. In this distribution \(\ln D\) is normally distributed. The normalized PSD, \(f(D)\) is given by Equation (21):

\[
f(D) = \frac{1}{\sigma D \sqrt{2\pi}} \exp \left( -\frac{(\ln D - \ln D_g)^2}{2\sigma^2} \right)
\]

where \(\ln D_g\) is the mean of \(\ln D\) and \(D_g\) is both the median and the geometric mean diameter; \(\sigma\) is the standard deviation of \(\ln D\) and it is called the geometric mean standard deviation. For small values of \(\sigma\) (\(\sigma < 0.14\)) the frequency curve can be closely approximated by a normal distribution.\(^{33}\) The \(n\)th moment of the log-normal distribution is given by Equation (22):\(^{54}\)

\[
J_n = \text{E}(D^n) = \exp n(\ln D_g) + (n\sigma)^2 / 2
\]

The number- \((D_N)\), volume- \((D_V)\), and turbidity- \((D_t)\) average diameters can therefore be calculated as (Equation 23):\(^{15}\)

\[
D_N = \frac{J_1}{J_0}; \quad D_V = \frac{J_3}{J_2}; \quad D_t = \left( \frac{J_6}{J_3} \right)^{1/3}
\]

The calculation of the moments of the estimated PSD from Equation (22) are correct only if the integration is done from \(D_{min}\) to \(D_{max}\) or, in practice, if the upper limit of the PSD, \(D_{max}'\), is such that when using \(f(D)\) from Equation (21), we have Equation (24):

\[
f(D) \frac{dD}{D_{max}} = 1.0
\]

Sometimes it may be known a priori (either from another method such as EM, DLS or particle chromatography, or by filtering of the suspension) that particle sizes smaller than \(D_{min}\) and/or larger than \(D_{max}\) do not exist. In these cases if we wish to estimate a log-normal envelope we can do so. In the parameter estimation all the integrations should be done between \(D_{min}\) and \(D_{max}\). A log-normal envelope, characterized by \(D_g\) and \(\sigma\), can be estimated; however, the PSD should be normalized before each iteration in the parameter estimation. Furthermore, the calculation of the various moments should be done using the explicit equation for the moments (Equation 25):

\[
J_n = \frac{D_{max}}{D_{min}} D^n f(D) dD
\]

and not Equation (22). The log-normal distribution estimated with previous knowledge of \(D_{min}\) and \(D_{max}\) is expected to be a more accurate estimate of the true PSD, since the contribution of tails of very large particles to the theoretically calculated specific turbidity is eliminated.

Note that if Equation (22) can be directly used, then the polydispersity of a suspension with a log-normal distribution is given by \(D_{max}/D_{min} = \exp(3\sigma^2)\) and the particle volume fraction is given by Equation (26):

\[
\phi = ND_g^3 \exp(4.5\sigma^2)
\]

Some workers\(^{4,5}\) had named as log-normal the distribution with the frequency function in Equation (27):

\[
f'(D) = Df(D)
\]

The two distribution functions are related by Equation (28):\(^{55–57}\)

\[
f(D) dD = f'(D) d\ln D
\]

Therefore, if \(f'(D)\) is used, then Equation (4) should be integrated with respect to \(\ln D\) and not with respect to \(D\). This distribution described by \(f'(D)\), has been called a ZOLD.

When applying Equation (15b), \(f(D)\) should be expressed on a weight basis. A log-normal distribution on a weight basis can be used.\(^{20,29,58}\) If the number distribution is log-normal, then the weight distribution is also log-normal with the same geometric standard deviation \(\sigma\).\(^{54,59}\) \(F(D)\) is the corresponding weight distribution for \(f'(D)\) of Equation (21). \(D_{wm}\) is both the median and the geometric mean diameter on a weight basis. \(D_{wm}\) and \(D_g\) are related by Equation (30):

\[
D_{wm} = D_g \exp(3\sigma^2)
\]

Heller et al.\(^{7,47,53}\) used another type of distribution that can be described by two parameters. However, the maximum polydispersity for that distribution is \(D_{W}/D_{N} = 1.5.\(^{15}\) Therefore, even though the distributional form can describe positively skewed distributions, it cannot successfully describe highly polydisperse systems.

4.5.2 No Assumptions on Shape of Particle Size Distribution

If no distributional form is assumed for \(f(D)\), then an alternative is to solve for \(f(D)\) at a finite number of points.\(^{6,60–64}\) In this approach, in the space of diameters from \(D_{min}\) to \(D_{max}\) we define \(P\) points (i.e. \(P\) diameters \(D_j\), \(j = 1: P\)) and we try to estimate \(f_j\) at the corresponding diameter \(D_j\). The number of \(P\) points must be less than
or equal to the number of specific turbidity or turbidity ratio measurements made.

Note that if the integrand of Equation (4) is discretized at $P - 1$ intervals, then turbidity at a given wavelength $\lambda_0$ can be approximated by Equation (31):

$$
\tau_{\lambda_0} \approx \sum_{j=1}^{P} f_j \gamma_j
$$

(Equation 31):

where $f_j \approx N_f(D_j) = N_j$ is the discretized PSD and $\gamma_j$ depend on the kernel and the quadrature equation used. $\gamma_j$ is evaluated at given $D_j$ from the Mie theory. Note that for the simple case that the suspension is a mixture of $P$ monodisperse suspensions with diameters $D_1, D_2, \ldots, D_P$, with relative number of particles $N_1, N_2, \ldots, N_P$, we have Equations (32) and (33):

$$
\gamma_{ij} = \pi D_j^2 K(\lambda_0, D_j)
$$

(Equation 32):

$$
\sum_{j=1}^{P} N_j = N
$$

(Equation 33):

When turbidity is calculated for $L$ wavelengths then Equation (31) can be written as Equation (34):

$$
\tau \approx \mathbf{f}^\top \mathbf{g}
$$

(Equation 34):

where $\mathbf{g} = \mathbf{[g_1, g_2, \ldots, g_L]}^\top$, and $\mathbf{f} = \mathbf{[f_1, f_2, \ldots, f_L]}^\top$ and $\mathbf{T}$ denotes transpose.

In the inverse problem, we have to estimate $\mathbf{f}$ from turbidity measurements $\mathbf{g}$ (Equation 35):

$$
\mathbf{g} = \mathbf{f}^\top \mathbf{T} + \mathbf{e}
$$

(Equation 35):

where $\mathbf{e}$ is the vector of errors (measurement errors plus errors due to discretization of the true distribution).

Solving Equation (35) is a linear algebra problem. The least-squares solution is Equation (36):

$$
\mathbf{f}_h = (\mathbf{T}^\top \mathbf{T})^{-1} \mathbf{T}^\top \mathbf{g}
$$

(Equation 36):

However, because the rank of $\mathbf{T}$ is incomplete, small errors in $\mathbf{g}$ result in large errors in the estimated parameters. For this reason, regularization methods should be used. A penalty function is introduced to the original least-squares problem (Equation 37):

$$
\min_{\mathbf{f}} \| \mathbf{g} - \mathbf{f}_h \|^2 + \xi q(\mathbf{f})
$$

(Equation 37):

where $\xi$ is a nonnegative parameter and $\| \|$ indicates the modulus. $q(\mathbf{f})$ could be the sum of squares, or the first or second differences, of the estimates. Eliçabe and García-Rubio added another term to the sum of squares of the second differences in order to force $f_1$ and $f_P$ to zero (Equation 38):

$$
q(\mathbf{f}) = \beta^2 (\mathbf{f}_1^2 + \mathbf{f}_P^2) + \sum_{j=2}^{P-1} ((2\mathbf{f}_j - \mathbf{f}_{j-1} - \mathbf{f}_{j+1})^2)
$$

(Equation 38):

Note that in this method one has to choose the location of $D_{\text{min}}$ and $D_{\text{max}}$ and the number of intervals but also the value of $\xi$. The choice of these parameters was discussed in detail by Eliçabe and García-Rubio.

This technique was tested with simulations for the estimation of unimodal and bimodal PSDs of varying breadth and mean diameter. Satisfactory results were reported for broad distributions with particle diameters in the micrometer range (distributions with $D_{\text{max}} = 1.45$ or 2.25 $\mu$m). For $m = 1.2$ the results were not satisfactory for distributions covering sizes from 50 to 325 nm, that is, a regime where a large number of latex particle diameters are expected to be found.

More attempts to resolve the PSD with no assumptions were reported later by other workers. Finally, an empirical method that relates turbidity measurements to particle size using latent variable methods has also been reported.

Gulari et al. tried to estimate PSDs in polystyrene suspensions $m \approx 1.2$, from a large number of turbidity measurements at the wavelength range between 300 and 800 nm. In each case, the unknown PSD was assumed to be the sum of 20 equally spaced delta functions ($\gamma_j$ from Equation 32). The height (mass fraction) and position of each diameter was optimized using a non-linear least-squares minimization procedure. During the analysis, the insignificant parameters are zeroed and the parameter matrix collapses until convergence is reached. The suspensions tested in that study were synthesized by Eliçabe and García-Rubio.
distributions, section 7.3) and (ii) for suspensions with 
\((m, \alpha)\) values where \(y\) does not change significantly with \(\alpha\). Readers should also keep in mind that the resolution of the method depends on the location of the assumed delta functions (number and width of \(\Delta D\) intervals) and of course on the number of measurements (observations) available.

In general, the estimation of \(f(D)\) at a finite number of points is expected to give satisfactory results only for certain suspensions (i.e. corresponding to certain \(m\) and \(\alpha\) values). The results will be questionable in \((m, \alpha)\) regimes where \(y\) does not change significantly with \(\alpha\). Kouri and MacGregor\(^{44}\) emphasized that more sophisticated deconvolution methods cannot overcome the limitations that turbidity ratio and specific turbidity have for particles in the \((m, \alpha)\) regimes where turbidity is simply proportional to a moment of the PSD. Several years later, Llorent et al.\(^{27}\) confirmed this by trying several deconvolution approaches to estimate the PSD in the Rayleigh regime; only turbidity-average diameters could be correctly estimated and not the PSD.

### 4.5.3 The Method of Moments

This method was presented\(^{9,10}\) as an alternative technique to solving for the PSD, but has some limitations for the particular application it was used. In this approach the term \(K(D/\lambda_m, n_p/n_m)\pi D^2/4\) in Equation (4) is approximated with a polynomial (Equation 41):

\[
K \left(\frac{D}{\lambda_m}, \frac{n_p}{n_m}\right) \frac{\pi D^2}{4} \approx \sum_{i=0}^{P} C_{i\delta} D^i
\]

(Turbidity can thus be expressed as a sum of \(P\) moments of the unknown PSD. Using \(P\) turbidity ratios \((P + 1\) turbidity measurements) one can estimate the \(P\) moments \((J_0\) of the normalized distribution is unity). The PSD is then represented analytically using a set of its moments, by modifying a gamma distribution which serves as a basis.

The method was applied for particle size determination in poly(vinyl acetate) latexes.\(^{9,10}\) First, the \(C_{i\delta}\) coefficients at each wavelength were estimated from Equation (41) by calculating the value of \(K_{scat} \pi D^2/4\) exactly from the Mie theory for a set of 20 diameters (between 0.04 and 0.8 \(\mu m\)) and setting the value of \(P\) equal to 6. Six \(C_{i\delta}\) were estimated for each wavelength. The procedure was repeated for seven wavelengths (350–800 nm).

As discussed in a critical review,\(^{15}\) the expansion of the scattering coefficient to a power series of \(\alpha\) (or for constant \(\lambda_m\), to a power series of \(D\)) is an approximation applicable for small \(\alpha\) and \(ma\) values. In these cases the coefficients of \(\alpha^i\) (or \(D^i\)) are known functions of the optical constants\(^{37}\) (i.e. no estimation of \(C_{i\delta}\) is necessary). The \(\alpha\) values corresponding to the diameters and wavelengths reported in the particular application\(^{9,10}\) were very large (\(\alpha\) as large as 9.5). For larger \(m\) and \(\alpha\) values the approximating equations for the calculation of \(K_{scat}\) include more involved functions\(^{37}\) of \(\alpha\) [or \(p = 2\alpha(m - 1)\)] than the simple power series expansion attempted in the method of moments. As discussed earlier, the term \(K_{scat} D^2\) can be set proportional to \(D^f\) for larger values of \(\alpha\), and the value of \(y\) changes as a function of the particle size. For poly(vinyl acetate) latexes in particular, and for a very wide range of \(\alpha\) values, the value of \(y\) is very close to 4.0. For most of the diameters used for the calculation of the above term in that study\(^{9,10}\) at each wavelength, the \(\alpha\) values were such that \(y\) was close to 4.0. It is clear that a reasonable value from the parameter estimation is expected only for \(C_{i\delta}\), since all the other coefficients are practically equal to zero. From the results reported by Kiparissides,\(^{9}\) only \(C_{i\delta}\) seems to have a consistent value for all the wavelengths; the estimated values of all the other coefficients change, both in sign and value, randomly.\(^{15}\) It should be clear that with meaningless estimates of the \(C_{i\delta}\) coefficients the correct estimation of the moments of the PSD is impossible.

### 5 ESTIMATION OF AVERAGE DIAMETERS

Several workers have tried to use turbidimetry to estimate only an average of the PSD of a polydisperse system. To do this they treat the system as monodisperse. That is, for specific turbidity, instead of using Equation (15a) they use Equation (12) and estimate a single, average diameter which is termed an “apparent diameter” (Equation 42):

\[
D_{av} = \frac{3}{2} \frac{\tau_{scat}}{\phi} \frac{K(\alpha_{av}, m)}{D_{av}}
\]

where \(\alpha_{av} = \pi D_{av}/\lambda_m\). \(D_{av}\) is the apparent diameter that always corresponds to the \(D_{av}\) average of the PSD.

The concept of the “apparent” diameter was introduced and theoretically explained in very careful work by Meehan and Beattie.\(^{4,5}\) They commented that the apparent diameter obtained by treating a polydisperse system as monodisperse corresponds to an average of the unknown PSD. They also concluded that different kinds of averages are yielded by different light scattering methods, and that the kind of average obtained by a light scattering method depends on the value of \(m\) of the suspension, the type of the PSD and the actual size of the particles in the suspension. Their comments have been corroborated by numerous reports\(^{3,4,7,13,16,29,66}\) where it is either discussed and/or shown experimentally that the type of average obtained from the apparent diameter depends on the turbidimetric technique used and the \(m\) and \(\alpha\) values of the suspension.
It has been suggested\(^7\) that the ratio of the apparent diameters estimated at two wavelengths can provide a rough idea of the polydispersity of the system. However, this is not always true. It has already been shown that, sometimes, especially for small \(m\) values (\(m \approx 1.1\)), the apparent diameters corresponding to very broad distributions or to bimodal distributions do not change significantly with the wavelength, leaving the impression that the system is monodisperse. Note that for monodisperse systems, the apparent diameters obtained from two different turbidimetric methods (i.e. specific turbidity, turbidity ratio) should be numerically very close to each other (i.e. equal, within experimental error).

Specific turbidity has been the only turbidimetric method used in the literature for the determination of averages of the PSD. This is because, as already discussed, it is the only turbidimetric method that can provide estimates of meaningful averages of the PSD (\(D_{13}\) averages) at some well-defined \((m, \alpha)\) regimes. The following averages may be obtained from specific turbidity: (i) the turbidity-average for very small particles \((\alpha < 0.5)\) and any value of \(m\), (ii) the volume–surface average for very large particles and any \(m\) value and (iii) weight-average for a combination of \((m, \alpha)\) values and \(m < 1.2\) which can be identified very easily for the system under investigation. In this section we discuss the use of specific turbidity for the estimation of meaningful average diameters. A critical discussion of several applications reported in the literature is presented, so that the readers can identify with situations closer to their needs.

### 5.1 Turbidity-average Diameters

These averages can be obtained from specific turbidity measurements, for suspensions with any value of \(m\), provided that all the particles in the suspension are small compared with the wavelength at which the turbidity measurements are taken (Rayleigh regime).

A practical application, where the growth of silver bromide grains is monitored on-line by following turbidity-average diameters, was reported by Haseler and Parkin\(^6\) for an Ostwald ripening process. They were careful to choose long wavelengths [infrared (IR) regime, 2.22 \(\mu\)m] so that the Rayleigh scattering theory could be applied even for the largest particles in their system.\(^15\)

Note that in the Rayleigh regime, if two particle suspensions have the same value of \(m\), the ratio of their specific turbidities measured at the same wavelength (see Equation 16) gives the ratio of their turbidity-average diameters, independent of the value of \(m\) (Equation 43):

\[
\frac{T_1/\phi_1}{T_2/\phi_2} = \left(\frac{D_{13}}{T_2}\right)_1^3
\]

This characteristic can be exploited to provide a fast and inexpensive tool to monitor particle growth in a suspension where the value of \(m\) is not accurately known. By simply measuring specific turbidity (turbidity and solids fraction) at each time interval, the relative increase in the turbidity-average diameter as a function of time can be recorded. From a measurement of the diameter or the PSD with another technique (which is independent of \(m\)) at the end of the process, we can back-calculate the turbidity-average diameter at each instant in time.

A report\(^28\) that a correct turbidity-average can be obtained for \(\alpha\) values as large as 4.74 from specific turbidity measurements should be treated with caution. These observations were rather coincidental with the polydispersions of the systems investigated, as explained in detail elsewhere.\(^15\) In the same work\(^28\) the term “weight” average was used for what in fact is the “turbidity” average, as can be deduced from the definition in the original publication,\(^67\) where EM results for the latex samples used in the later study\(^28\) were presented.

### 5.2 Volume–Surface-average Diameters

Volume–surface-average diameters have been estimated in the literature from specific turbidity measurements of suspended particles that were very large compared with the wavelength (\(K_{\text{scat}} \approx 2\)). It should be noted that, although the value of the oscillating \(K_{\text{scat}}\) stays very close to 2.0 for large \(\alpha\) values, the error by assuming it to be equal to 2.0 is small only for very large \(\alpha\) values (i.e. the error is within 3% for \(\alpha > 800\) and within 1% for \(\alpha > 2000\)) (see Table 2). For \(\alpha\) values around 200–260, where some of the cases reported in the literature are, the error of assuming \(K_{\text{scat}} = 2.0\), depending on the spread of the distribution, could be as large as 6% for \(m = 1.2\) and 9% for \(m = 1.1\) (at these \(\alpha\) values \(K_{\text{scat}}\) still depends on \(m\)). Therefore, depending on the range of \(\alpha\) values covered by the true distribution, the estimated \(D_{13}\) average diameter could be within 10% error of the true value.

Bagchi and Vold\(^69\) showed experimentally that for very large particles, the specific turbidity varied linearly with the inverse of the volume–surface-average diameter (1/\(D_{13}\)). However, a linearity observed with respect to the inverse of other averages was coincidental and attributed to the fact that the degrees of polydispersity of the latexes investigated were very similar.\(^15\) Kubota et al.\(^68\) discussed this coincidental linearity and presented more experimental results from suspensions of various polydispersities, verifying that only the specific turbidity vs (1/\(D_{13}\)) curves are linear, as was theoretically expected.

Kourt\(^15\) showed that a claim by Dobbins\(^69\) and Dobbins and Jizmagian\(^70\) that the volume–surface-average diameter can be obtained from one specific turbidity measurement in any particle size regime cannot
be supported. Their observations, that “the specific turbidity is primarily dependent on the $D_{32}$ diameter and only weakly dependent on the type of the distribution”, were shown to be coincidental with the types of distributions that they used for their investigation. These distributions had also their weight averages close to each other and all of them included particle sizes in the same range. Similar claims by Haseler\(^{15}\) were also discussed in Kourt\i\(^{15}\). It was shown that in the examples reported by Haseler,\(^{19}\) the estimated $D_{32}$ was close to the true value because the location of the whole distribution was correctly estimated, and not because specific turbidity is always expected to give a correct $D_{32}$ as claimed.\(^{69,70}\)

It has been suggested\(^{71}\) that the specific turbidity of a polydisperse system can be expressed as Equation (44):

$$\frac{\tau_{\alpha}}{\Phi} = \frac{3}{2} \frac{K(\alpha_{av}, m)}{D_{32}} \tag{44}$$

where (Equation 45):

$$K(\alpha_{av}, m) \approx \int_0^\infty D^2 f(D) d(D) = \int_0^\infty D^2 K(\alpha_{av}, m) f(D) d(D) \tag{45}$$

where $\alpha_{av}$ corresponds to an average diameter $D_{av}$. It was suggested that the two parameters $\alpha_{av}$ and $D_{32}$ can be used to interpret turbidity data over a wavelength range. The $D_{32}$ diameter will correspond to the true PSD whereas $\alpha_{av}$ will correspond to the average diameter “seen” by the measurements “averaged over the wavelength range”. However, by definition, the only correct form for the calculation of an average diameter from specific turbidity measurements is that of Equation (42). Equation (44) is valid only for very large diameters, where $K(\alpha_{av}, m) = 2$, independent of particle size. In any other case if we try to estimate the two parameters ($\alpha_{av}$ and $D_{32}$) in Equation (44), “over a range of wavelengths”, these estimates will be highly correlated. Their numerical values will depend on the wavelength range used and the $D_{32}$ estimate will not, in general, correspond to the volume–surface-average of the true PSD.

### 5.3 Weight-average Diameters

For suspensions with small values of $m$ (usually $m < 1.15$) and particle sizes corresponding to certain $\alpha$ values (i.e. for $m = 1.05, 3 < \alpha < 14$; for $m = 1.15, 3 < \alpha < 6$), the apparent diameters obtained from specific turbidity measurements are numerically close to the weight-average diameter, $D_w$. This average is essentially the only correct estimate of the particle size that can be obtained for polydisperse systems in these ($m, \alpha$) regimes. If users know the value of $m$ of their suspensions they can devise simple ways to obtain this average. For example, it has been observed\(^{15}\) that the mean value of the apparent diameters from specific turbidities at 600 and 400 nm, obtained for a variety of polydisperse poly(vinyl acetate) latexes ($m \approx 1.1$) with different distributions (unimodal, multimodal) in the submicrometer regime, is numerically very close to the true weight average of the distribution. That means that for $m = 1.1$ the weight average from submicrometer particle suspensions can be estimated very simply, from two specific turbidity measurements at 400 and 600 nm. Similar heuristic rules could be derived for other suspensions with small $m$ values.

Cheesman,\(^{72}\) for example, suggested a technique in which the specific turbidity is measured at several wavelengths and the apparent diameter ($D_{av}$) is estimated for each wavelength. Then the corresponding $\alpha_{av}$ values are calculated ($\alpha_{av} = \pi D_{av}/\lambda_{av}$) at each wavelength. The apparent diameter that gives $\alpha_{av}$ near the $\alpha$ value of the first point of inflection of the $K_{scat}$ vs $\alpha$ curve is chosen to be the weight-average diameter (for $m = 1.1$, this $\alpha$ value was chosen 2.7 and for $m = 1.2$, it was 2.2). The apparent diameter selected this way in the polydisperse systems he studied was within 4% of the true weight-average diameter.

The observations of Cheesman can be explained theoretically. At the $\alpha$ value at the inflection point (see peaks of the first ripple of the $y$ vs $\alpha$ curve in Figure 2) the value of $y$, for almost any value of $m$, is close to 4.5. If the weight-average diameter corresponds to this $\alpha$ value, then the $\alpha$ values for the individual particle diameters of the distribution are located around it and the value of $y$ varies between 4 and 4.5. Hence in this technique, the wavelength is chosen such that the entire distribution is brought to an $\alpha$ regime where $y$ is close to 4.0 and the apparent diameter is the weight-average diameter.

As has been pointed out\(^{44}\) the fact that the weight-average diameter of suspensions can be correctly estimated even though the PSD determination is impossible is a very useful property of the specific turbidity. It was suggested\(^{44}\) that this property could be utilized for practical applications, in situations where following an average diameter is sufficient to monitor the progress of a process. An example would be on-line particle size measurements to monitor the progress of polymerization reactions. Gossen\(^{23,46}\) and Gossen and MacGregor\(^{24}\) used this suggestion and applied specific turbidity on-line to monitor weight-average diameters of poly(vinyl acetate) particles during latex production. The results reported\(^{23,24,46,73}\) show good agreement between the weight-average diameters obtained by turbidimetry and those obtained by on-line DLS.

### 5.4 Other Applications of Turbidimetry

The dependence of turbidity on particle size can also be exploited in other ways than its conventional use in particle size determination. Kourt\i\(^{15}\) suggested that simple
turbidity measurements at one wavelength can be used to monitor polymerization processes in order to detect the onset of several events, as for example the beginning of the reaction in latex systems (i.e. the end of induction period) or the onset of agglomeration. By following turbidity measurements at one wavelength during the emulsion polymerization of vinyl acetate in a continuous laboratory-scale reactor, Kiparissides et al. [9,10] could detect whether the reactor was operating under steady-state conditions or under oscillations. Turbidity measurements at 400 nm were used by Kourt[15] to follow qualitatively the effect of several variables on particle size during vinyl acetate emulsion polymerizations. Turbidity measurements at one or more wavelengths (and reduced to the same degree of dilution) can also be used for routine operations to monitor the progress of the reaction and detect any deviations from a known desirability measurements at one or more wavelengths can also be used for routine operations to monitor the progress of the reaction and detect any deviations from a known desirable path. Finally, Crawely et al. [74] discussed the use of turbidity measurements at several wavelengths in studies of crystallization, agglomeration and attrition.

6 PROCEDURAL DETAILS

6.1 Instrumentation and Forward Scattering

The turbidity of a suspension can be measured very easily in a laboratory or a plant environment. Very often spectrophotometers in the UV/VIS range are utilized for this purpose. A dilute suspension is inserted in the cell of the spectrophotometer. We have (Equation 46):

\[ \tau_{\lambda_0} = 2.303 \frac{A}{T} = \frac{1}{l} \ln \left( \frac{100}{T} \right) \]  

(46)

where \( A \) is the absorbance reading, \( T \) is the percent transmittance at wavelength \( \lambda_0 \) and \( l \) is the optical path (i.e. width of cell). There are also reported applications where turbidity measurements at longer wavelengths, in NIR regime, [6,16,17,19,26] were used for particle size determination. Sometimes, certain modifications may be necessary [19] in the instruments used to measure turbidity so that forward scattering is rejected and theoretical calculations of turbidity can be legitimately compared with the measured values. This is because for the determination of particle size from turbidity measurements, it is assumed that the detector measures the attenuation of the beam of the source light. However, all the spectrophotometers measure the attenuated light from the source plus a certain amount of light scattered at small angles. Forward scattering will add error to the value of the true turbidity. Reports in the literature [34] mention that the larger the particles the greater is the possible discrepancy between the true and the measured (or apparent) turbidity, but for small particles and particles comparable to the wavelength the difference between the true and apparent turbidity should be minute. Bohren and Huffman [75] suggested that although conventional spectrophotometers are not usually designed to reject scattered light at small angles, such instruments may be adequate for scattering measurements if the particles are not too large. For monodisperse polystyrene latexes \( (m = 1.2) \) with diameters of 109, 312 and 1050 nm and turbidity measurements at wavelengths between 300 and 600 nm, they used a conventional spectrophotometer, suggesting that the forward scattering should not be significant. Walstra [76] suggested that sometimes errors attributed to forward scattering [18] were in fact due to extremely high optical densities that the investigators had included in their results.

The brief analysis that follows illustrates the consequences of the error added to the value of the true turbidity due to forward scattering. The effect that an error in the measured turbidity value has on the estimated particle size depends on the turbidimetric technique used and the \( (m, \alpha) \) values of the system and it cannot be generalized. The turbidity ratio utilizes two turbidity measurements at different wavelengths, therefore the error due to forward scattering is introduced twice in this method, but only once in the specific turbidity. In Figure 5 we plot [15] as a function of \( \alpha \), for two different \( m \) values, the percentage error in the estimated diameter in monodisperse suspensions for a 3% error in the measured specific turbidity. Note that the effect changes with the \( (m, \alpha) \) combination. For \( m = 1.2 \) and \( \alpha \) values near the specific turbidity maximum (which for \( m = 1.2 \) occurs at \( \alpha = 7.33 \)), the error becomes very large. However, for \( \alpha \)  

![Figure 5 Percentage error in the estimated particle diameter of monodisperse suspensions plotted as a function of \( \alpha \) for \( m = 1.1 \) and 1.2 when there is a 3% error in the specific turbidity measurements.](image-url)
values less than 4.0 the error in the diameter is the same for $m = 1.1$ and 1.2, and it is approximately 4.0%. For water medium ($n_m \approx 1.33$), a value of $\alpha = 4$ corresponds to $D/\lambda_0 \approx 1$ ($\alpha = 4 = \pi D n_m/\lambda_0$), which means that for particles smaller and comparable to the wavelength the error is small. Therefore, if the error due to forward scattering introduces a $3-4\%$ error in specific turbidity, then for particles comparable to $\lambda_0$ the effect on particle size should not be significant, and this would explain the observations reported by various workers. A final note on size should not be significant, and this would explain the K

empirical approaches have been suggested to account for the scattering introduces a $3-4\%$ error in specific turbidity, error is small. Therefore, if the error due to forward scattering is $3\%$ due to either a wrong solids fraction measurement or to forward scattering, and would have the same effect on the estimated size).

Errors in turbidity measurements due to forward scattering are discussed in a number of references, where suggestions are given for the modification of the spectrophotometers. Also, several empirical approaches have been suggested to account for the difference between true and apparent turbidity. For example, a correction factor ($R$) can be estimated for several suspensions with known particle diameters; $R$ is equal to the ratio of the measured to the theoretically expected turbidity. This factor can then be used for unknown suspensions, but with $(m, \alpha)$ values in the same range for which it was estimated. In another approach, a calibration was used to relate apparent specific turbidity with the true particle size for large latex particles where forward scattering is significant.

Users can assess the accuracy of the turbidity measurements of their spectrophotometers by comparing the experimental values with theoretically calculated values for monodisperse suspensions with known diameters, covering the range of $(m, \alpha)$ values that they plan to analyze. Before proceeding to any modifications one should judge whether the accuracy is satisfactory for the purpose of the study to be carried out using the turbidimetric results. For example, if the purpose of the study is to use the method as a reproducible and inexpensive way to monitor particle size during a reaction, then the accuracy of the spectrophotometer with no modifications may be satisfactory, and similarly if the objective is to detect the qualitative effect of various parameters (emulsifier, impurities) on the particle size of the latex. For other applications that require more accurate determinations of larger particles, one may consider modifications of the spectrophotometer and the use of a correction equation that accounts for the angle of acceptance of the detector for the calculation of the scattering coefficient. Kourtí used two spectrophotometers without modifications for diameters up to 400 nm and suspensions with $m = 1.1$ and 1.2: a Hewlett-Packard Model 8450A at wavelengths of 350–700 nm and a bandwidth of 2 nm and a Bausch and Lomb (now Spectronic Instruments) Spectronic 20 at wavelengths of 380–580 nm and a bandwidth of 20 nm. The accuracy of the method was tested by estimating the size of monodisperse suspensions with known diameters and also by comparing the size estimated by turbidimetry with that measured by EM and DLS. For numerous unknown samples, the diameters estimated by turbidimetry were in very good agreement with those measured by DLS and EM. Forward scattering did not introduce any problems.

Gossen and MacGregor used for on-line measurements in a pilot-plant environment a Bausch and Lomb single-beam Spectronic 20 equipped with a cylindrical Pyrex flow-through cell with a 1 cm pathlength, without any modifications for forward scattering. The incident beam had a bandwidth of 20 nm and the wavelength was 400 nm. Weight-average diameters up to 200 nm obtained during latex production were in very good agreement with weight-average diameters obtained by on-line DLS, and a change in $D_w$ of the order of 10 nm was detectable. The accuracy of the results was considered satisfactory for their objective to monitor changes in the particle size due to process disturbances.

### 6.2 Refractive Indices of the Particles and the Medium

Turbidity is a very strong function of the optical properties of the particle suspension, that is, the ratio of the refractive index of the particles to that of the medium, $m$, and the refractive index of the medium, $n_m$. The latter is used for the calculation of $\lambda_m$ and consequently the calculation of $\alpha$. For the correct determination of the particle size the values of these properties must be accurately known. The values of the refractive indices for different materials can be found in relevant handbooks. Refractive indices can also be directly measured, or estimated using a combination of techniques as described below.

Llorente et al. used a Bellingham Abbé 60 refractometer to measure the refractive index of latex particles, $n_p$, required to calculate $m$ for their work. The refractive index of the polymer film was measured at several wavelengths. They then used the measured values to estimate the constants for a Cauchy equation that expresses $n_p$ as a function of the wavelength $\lambda_0$ (Equation 47):

$$n_p(\lambda_0) = A + \frac{B}{\lambda_0^2} + \frac{C}{\lambda_0^4}$$

(47)

This equation was subsequently used to calculate $n_p$ at other wavelengths.

If the value of the refractive index of the medium $n_m$ is known but $n_p$ and therefore $m$ are not known, it may be possible to estimate $m$ directly using a combination of
TURBIDIMETRY IN PARTICLE SIZE ANALYSIS

Techniques. Kourtis\(^{15}\) suggested that, since turbidimetry is very sensitive to the value of \(m\), it is probably the best method to “estimate” the values of \(m\) as a function of wavelength for a specific suspension. Suppose we wish to estimate the value of \(m\) for suspensions of polybutadiene particles in water. Using a monodisperse suspension of polybutadiene particles in water with known diameters (estimated by EM or DLS), the scattering coefficient and therefore \(m\) can be calculated from the specific turbidity measurements at one wavelength (provided \(n_m\) is known).

By measuring specific turbidities at more wavelengths one can estimate the dependence of \(m\) on wavelength. The advantage of this approach is that the value of \(m\) for a particular suspension is measured in the environment in which it will be used. This may be more meaningful than, say, using a latex film to measure the refractive index of particles and dividing by the refractive index of medium. Once \(m\) has been measured it can be used for suspensions of the same material (i.e. polybutadiene in this example), but of course for any particle sizes or PSD. DLS is an excellent method for this purpose because the particle sizes can be measured in suspension and for monodisperse particles DLS is independent of the refractive index. Another method to determine optical constants would be angular light scattering.

Sometimes the medium may not be a clear substance but may have additives. In latex samples, for example, cross-linking may be added to the water medium, or monomer may be dissolved in it if the samples are withdrawn at low monomer conversions. In these cases the refractive index of clear water cannot be used. The refractive index of the medium for a given concentration of water-soluble monomer (or other substance present in it) can be read directly from a calibration curve of refractive index as a function of the concentration of monomer in water. Such calibration curves can be easily constructed from refractive index–concentration increments obtained from differential refractometers. In high dilutions the effect of monomer on the refractive index of the medium is usually negligible.

6.2.1 Inhomogeneous Particles/Latex Particle Applications

Sometimes the particles in the suspension may not be homogeneous. Examples from latex systems are carboxylated particles that swell in water, particles swollen with monomer in latex samples withdrawn at low conversions and particles produced by core and shell polymerizations. There are several issues related to determining the optical properties of such particles and research is active on light scattering by inhomogeneous particles.\(^{81–83}\)

For monomer swollen particles, or particles produced by core and shell polymerizations, one approach is to calculate the value of \(m\) by treating the particles as coated spheres. For coated spheres the refractive index ratio can be calculated as \(m = m_1 v_1 + m_2 v_2\), where \(m_1\) is the ratio of the refractive index of the core to the medium and \(v_1\) is the volume fraction of the core; \(m_2\) and \(v_2\) are the corresponding values for the coating. \((v_1 + v_2 = 1.0)\). This approximation is not very accurate for thin coatings. In the above approach, for monomer swollen polymers, the volume fractions of the monomer and polymer are treated as core and coating respectively. It should be emphasized that this is an approximation, and the true morphology of monomer swollen particles may be different than a core and coating approximation. Bohren and Huffman\(^{75}\) also presented an algorithm to calculate the scattering functions of coated spheres (consisted of homogeneous core and homogeneous coating of uniform thickness) and they discuss the limitations of this algorithm, in general, for anisotropic spheres. For very accurate calculations, these approximations to estimating the value of \(m\) for core and shell particles must be checked experimentally. This can be done as mentioned earlier by using another method (i.e. DLS) to estimate the particle size and then using turbidimetry to estimate the value of \(m\) for particles with known polymer composition. The above calculations should be performed on monodisperse suspensions. A calibration curve could then be constructed to give the value of \(m\) as a function of the polymer composition in the particle. If DLS is used to verify the particle size of monomer swollen particles, the same degree of dilution must be used to make sure that the same particle size is measured (because monomer is dissolved in water and extracted from the particle with high dilutions).

For monomer swollen particles and carboxylated particles that swell in water, both the density and the refractive index depend on the degree of swelling and appropriate corrections should be made. In monomer swollen particles, the amount of monomer associated with the particles (and therefore the refractive index of the particle and the medium) depends on the conversion, the solubility of monomer and the degree of dilution of the original sample.

Latex produced by multicomponent polymerization is also a case where the calculation of the refractive index of the particles may present difficulties. The refractive index depends on the polymer composition and may change during the reaction due to composition drift. Therefore, calibration may be needed to relate the refractive index of the particles to their composition (by taking into account the conversion of the monomers at the time of sampling). When monitoring particle growth with on-line turbidimetry during multicomponent polymerizations, on-line gas chromatography can be utilized to provide
information on the composition of the particles. The refractive index can then be calculated from the particle composition utilizing some type of calibration. On-line densitometry combined with on-line gas chromatography can provide information on the particle volume fraction, \( \phi \). More details on this topic can be found in Kourtis.(15)

6.3 The Choice of the Wavelengths

As discussed earlier, the successful determination of the PSD or of an average particle size of a suspension depends on the \( m \) and \( \alpha \) values of the suspension and the turbidimetric technique used. The refractive index of the medium and therefore the value of \( m \) of a suspension can be altered by adding other substances to the medium [e.g., glycerol(5,16)] provided that these substances do not affect the particle size. The range of \( \alpha \) values covered by the PSD can also be manipulated by changing the wavelengths at which the turbidity measurements are taken. As a general rule, wavelengths widely separated from each other should be used when the estimation of the full PSD is required. In this way the range of \( \alpha \) values covered by the PSD changes significantly from one wavelength to another (the \( y \) exponent changes) and the probability of the turbidity being proportional to the same moment of the PSD at both wavelengths is reduced. It should be noted, however, that when wavelengths widely separated from each other are used, the value of \( m \) at each wavelength must be accurately known; using a constant \( m \) may result in false estimates.(15) If only one value for \( m \), estimated at, say, \( \lambda_0 \), is available and must be kept constant for all the wavelengths, then wavelengths on either side of \( \lambda_0 \) (i.e. both shorter and longer) and as close to \( \lambda_0 \) as possible must be used.

To keep wavelengths widely separated, several workers chose one wavelength in the UV/VIS range and one in the IR region. The first (1.7 \( \mu \)m)(16,17) and the second (2.22 \( \mu \)m)(19) IR transmission windows for water have been the choices for long wavelengths. Most workers have avoided wavelengths below 400 nm where some particles may absorb light and wavelengths where the medium absorbs light.

Eliçabe and García-Rubio(62) used wavelengths in regimes where particles absorb to resolve the PSD for a computer-simulated polystyrene latex example, where clear water was assumed to be the medium. The resolution of the PSD was improved. However, in practical situations for latex particle size analysis, it is preferable to avoid working at short wavelengths where absorption occurs (e.g. the styrene ring absorbs at 269.5 nm). In latex samples withdrawn at low monomer conversions, residual monomer which absorbs light at certain short wavelengths may be present in the particles and extracted owing to dilution in the medium. As a consequence, if particle size determination is attempted at these short wavelengths without accounting for the distribution of the absorbing monomer between the medium and the particles, the results may be questionable. However, calculating the monomer distribution is tedious and requires a knowledge of conversion, partition coefficient of the monomer between the water and the polymer phase and the degree of dilution. It is clear that using short wavelengths is not practical if the objective is to follow particle growth during the reaction.

6.4 Preparation of Samples

In particle size determination by light scattering methods, it is usually assumed that the scattering by an array of particles is incoherent (the particles are randomly positioned in space to avoid mutual polarization) so that the scattering functions corresponding to an isolated particle may be used, and also that there is no significant multiple scattering. These conditions are practically met(33) when turbidity measurements are taken with sufficiently dilute suspensions. In practice this is achieved by diluting the suspension and working at a concentration range where the turbidity, at the shortest wavelength to be used, varies linearly with the particle concentration. Figure 6 shows how turbidity changes with concentration. The shorter the wavelength, the lower is the concentration of suspended solids required to avoid multiple scattering.

The fact that the sample needs to be diluted may have an effect on the particle size in certain cases. For example, in latex samples withdrawn at low conversion, polymer particles swollen with monomer may change size by changing the degree of dilution, and this should be taken into account. Also, for latex particles stabilized

---

![Figure 6 Turbidity plotted against solids concentration in the sample: linearity check.](image-url)
by ionic or nonionic emulsifiers or other groups, the user must be careful to dilute the sample without risking destabilization. Some emulsifier (the same as the one used in the latex production) must be added to the diluting medium to prevent destabilization. Samples prepared in this way remained stable for a long time; turbidity measurements taken 3 years after the samples were prepared showed no difference within experimental error with measurements taken for those samples when they were freshly prepared. Kourtí(15) discussed in detail other considerations for latex particle size determination, for both off-line and on-line applications.

6.5 Particle Volume Fraction for Specific Turbidity
Particle volume fraction is measured by gravimetric analysis. The weight of the dry solids per cubic centimeter \( c \), \( g \text{ cm}^{-3} \) is measured and converted to volume fraction using the density of the particles \( \rho \), \( g \text{ cm}^{-3} \); \( \phi = c/\rho \). Particle volume fraction is usually measured on undiluted samples. The particle volume fraction corresponding to the diluted sample on which the turbidity measurement is taken is calculated by taking into account the degree of dilution. Therefore, the degree of dilution must be known very accurately. Particle volume fraction for on-line applications can be measured by densitometry.\(^{21,23,24}\)

The sensitivity of the estimated particle size to such errors has been investigated by several workers. The results are briefly summarized in the following sections.

7.1 Error in Measurements
The effect of measurement errors on the estimated particle size depends on the technique used (specific turbidity or turbidity ratio) and on the \( (m, \alpha) \) values of the system and cannot be generalized, as illustrated in the following. Kourtí(15) reported an average error of 0.4% in the repeatability of transmittance readings. Such an error is translated to an average 2% error in specific turbidity. For the \( (m, \alpha) \) values used, with \( m = 1.1 \) and \( \alpha < 3.5 \) this would translate to a maximum error of 2% in the particle diameter for monodisperse suspensions. If a different technique, say turbidity ratio, was used for the same \( (m, \alpha) \) regime, then from a small bias of +0.5% on the transmittance readings at both wavelengths (the same bias would be the case due to forward scattering) the error in the particle size for monodisperse particles can be 2–3%. For the same size regime, if instead of the bias the error was random (±0.5%), then the error in the particle size can be as large as 9%. Because the effects of turbidity measurements on particle size cannot be generalized over \( (m, \alpha) \) values, a good practice for users would be to construct a curve such as that in Figure 5 for the \( m \) value of the suspensions with which they plan to work. The effect of a certain percent error in specific turbidity (or turbidity ratio) on the estimated particle size can be calculated with simulations for a wide \( \alpha \) range. Then, by changing the value of \( \alpha \) used (by changing the wavelength), they can move the system to a regime where measurement errors would not affect the particle size significantly.

The effect of measurement errors on the estimated PSD in polydisperse systems was the subject of a detailed study\(^{15,52}\) and it has been shown to depend on the technique used (specific turbidity or turbidity ratio) and on the \( (m, \alpha) \) values of the suspension. As discussed in section 4, the estimation of full PSD is impossible within experimental error in some \( (m, \alpha) \) regimes. However, in these regimes, if specific turbidity is used, an average diameter can be correctly estimated and the effect of measurement error on this average diameter is not large. In regimes where only the weight-average diameter can be estimated, for a random error of ±3% in specific turbidity at three wavelengths, the maximum error was for a weight average 5%. As a comparison the maximum error for the number average in these regimes was 40%.\(^{15}\)

7.2 Error in the Value of the Refractive Index Ratio, \( m \)
Kourtí(15) studied the effect that errors in the value of \( m \) have on the estimated PSD. It was concluded that
turbidimetry is sensitive to such errors but the magnitude of the effect on the estimated PSD depends on the \((m, \alpha)\) values of the suspension. In certain \((m, \alpha)\) regimes, the effect that the error in \(m\) has on the estimated parameters of the PSD is comparable to the effect of turbidity measurement errors, whereas in others it is much higher. In regimes where the \(y\) exponent does not change significantly with the particle size, the errors in the value of \(m\) had a larger effect on the estimated size than turbidity measurement errors. Therefore, observations reported in the literature on the magnitude of this effect cannot be generalized for any \((m, \alpha)\) values. For example, the observation of Wallach and Heller\(^7\) that "the error of the disregard of the dispersion of \(m\) is less that experimental error" was simply a coincidence of the \((m, \alpha)\) values of the system with which they were working. Whenever there is uncertainty in the value of \(m\) of the suspension to be analyzed, a sensitivity analysis should accompany the results, to indicate the degree of confidence. Alternatively, the results should be corroborated with another method.

Sometimes, the dependence of the refractive index of the medium, \(n_m\), on the wavelength is known, but only one measurement for the refractive index of the particles, \(n_p\), at one wavelength \(\lambda_0\) is available. If this is the case, it is recommended that a constant \(m\) (calculated at \(\lambda_0\)) is used at all the wavelengths, and not a variable \(m\) calculated with constant \(n_p\) and wavelength-dependent \(n_m\). For water medium, a wavelength-dependent \(n_m\) decreases with longer wavelengths and using constant \(n_p\) will force \(m\) to increase with longer wavelengths (when it is expected to decrease); this in turn means significant errors when analyzing real data since the estimated particle size moves in the opposite direction to the true value. Finally, when a constant value of \(m\) is used, the error is smaller if the turbidity measurements are taken at wavelengths both shorter and longer and as close as possible to the one at which \(m\) was measured.

In all cases, however, if the wavelength-dependent \(n_m\) is known, it should be used to calculate the value of \(\lambda_m\) and therefore \(\alpha\) for the scattering coefficient calculation.

7.3 Error in the Assumed Distributional Form
The main criticism in the literature about approaches that attempt to recover the PSD by assuming a type of the distribution (i.e. log-normal, Gaussian, etc.) is that the assumed distribution may be very different from the true one. When a distributional form is assumed, a constraint (i.e. the shape of the distribution) is forced upon the solution. The expected result is a PSD with the assumed shape that will envelope the true distribution; the details of the true PSD are not expected to be resolved. The estimation of the location of the main body of the distribution is therefore the most satisfactory result expected in this case.

The error introduced in the estimated PSD when the assumed distributional form is different from the true one has been studied either experimentally or with simulated cases by several workers. Wallach and Heller\(^7\) tried to estimate the PSD of three suspensions with positively skewed, negatively skewed and symmetrical distributions, using the turbidity ratio method and assuming a distributional form which can describe only positively skewed distributions. In the cases of negatively skewed and symmetrical PSDs, the estimates of the parameters chosen to describe the distribution had a significant error; however, Kourti\(^{15}\) reported that a careful examination of those results showed that the estimated PSD enveloped (i.e. recovered correctly) the main body of the true distribution. This behavior was expected since the polydispersities of the three synthesized distributions and of the assumed distribution were very small; no distributions with very long tails to small or large particles were studied.

In an extensive simulation study, Kourti\(^{15}\) investigated the error introduced in the estimated PSD when the shape is assumed to be log-normal. Specific turbidities were calculated (at 400, 500 and 600 nm) for several polystyrene suspensions of submicrometer particles with several types of continuous distributions: positively skewed, negatively skewed, symmetrical, bimodals with broad peaks and overlapping tails. The polydispersities were from 1.04 to 1.9. Then, from these calculated specific turbidities and assuming a log-normal form, the PSD of the suspension was re-estimated. The following conclusions were drawn that are valid for the estimation of the PSD (using the specific turbidity method) of suspensions of submicrometer particles, excluding the Rayleigh regime where only \(D_r\) can be estimated and the \((m, \alpha)\) regimes where specific turbidity can only give \(D_m\):

- When the true distribution is continuous with no long tails to either small or large particles, the estimated distribution with a log-normal assumption will cover the main body of the true PSD when plotted on a number basis.
- On a weight basis the main body of the true distribution will be covered by the estimated log-normal distribution, in all cases, even when the true PSD has long tails.
- The weight-average diameter of the distribution estimated with a log-normal assumption is very close to the true weight average of the suspension, even in cases that the true distribution is significantly different from a log-normal shape. For the cases studied the weight-average diameter of the PSD estimated when assuming a log-normal form (on a
number or weight basis) was, in general, within 1.0% of the weight average of the true PSD.

These conclusions are corroborated by experimental results reported by Haseler\(^{19}\) for submicrometer polystyrene suspensions. They also agree with the observations of Yang and Hogg.\(^{20}\) These authors also studied experimentally the error on the estimated PSD when the shape of the true distribution is different from the assumed log-normal form. The estimated distribution was compared with the true one on a weight basis; the distributions studied were broad, covering particle sizes from 0.1 to 10.0 µm. They found that “the estimated distribution conformed closely to the central portion of the true distribution (on a weight basis) and was not strongly biased towards either of the tails”.

It should be noted that when using Equation (31) to estimate \(f_j\) for diameter \(D_j (j = 1, 2, \ldots, P)\), instead of assuming a form for the PSD, there are also assumptions involved. These include the choice of the parameter in the regularization algorithm and the number of points to which the PSD will be discretized and the location of the \(D_j\). The number of points depends on the available number of turbidity measurements at different wavelengths. For a study on the effect that the number of discrete points at which \(f_j\) is estimated has on the estimated PSD, readers are referred to Eliçabe and Garcia-Rubio.\(^{62}\) In that study the true distributions were all simulated continuous distributions.

There is also the question of whether there is an advantage in proceeding with collecting more wavelengths and trying to estimate the distribution using Equation (31). In the case of continuous unimodal distributions, the resolutions of the two techniques under experimental error seem to be comparable; an assumption of a log-normal shape that will provide the main body of the true PSD and the true \(D_m\) may be sufficient for most routine applications in the submicrometer and lower micrometer region.

### 7.3.1 The Resolution of Bimodal Distributions

Regularization methods have the potential to recover the PSD without assuming any shape, if the true distribution is a bimodal one with two broad peaks, such as that shown by the histogram in Figure 7. Eliçabe and Garcia-Rubio\(^{62}\) resolved such a simulated distribution where the particle diameters covered a very wide range from 50 to 2550 nm; in that study wavelengths in the absorption range were included for the turbidity measurements. For such bimodal distributions, the regularization methods have the capability (provided that there are enough turbidity measurements) to uncover the true shape whereas the log-normal assumption will always produce an envelope around the main body, as shown in Figure 7. Distribution I

![Figure 7 Bimodal distribution as resolved by a log-normal assumption.](image)

in Figure 7 shows the distribution (on number basis) estimated with a log-normal assumption for polystyrene suspensions \((m = 1.2)\) where the true distribution (shown by the histogram) was in the size range between 0.0 and 0.8 µm \((D_0 = 0.0)\). Distribution II is the log-normal PSD estimated when the size range for the true distribution was between 4.0 and 1.2 µm \((D_0 = 0.4)\). Note that although the two histogram distributions have the same breadth \((0.8 \mu m)\), in case II the distribution has a smaller polydispersity (since the average size is larger). Note that in case I the estimated log-normal distribution tends to envelope only the larger particles of the true distribution, whereas in case II it uncovers the correct range but of course cannot resolve the bimodal shape.

When dealing with bimodal distributions one should keep in mind that the contribution of small particles to the value of the specific turbidity could be totally obscured by the contribution of the large ones, depending on their \(\alpha\) values (relative to the \(\alpha\) value location where the peak of \(K_{cat}\) occurs). As an example, assume a polystyrene suspension \((m \approx 1.2)\) with a bimodal distribution which consists of two monodisperse populations with \(D_1 = 0.6 \mu m\) and \(D_2 = 0.1 \mu m\), and where the number of small particles is 10 times the number of the large ones \((N_2/N_1 = 10)\). The contribution of the small particles to the total specific turbidity at 400 nm is only 0.46%. Hence the presence of small particles will cause less disturbance than the experimental error even though there are 10 times more small than large particles. In such a case it is not expected that the regularization methods will produce the correct solution within experimental error.
Wallach and Heller\textsuperscript{(7)} suggested using combinations of two distributions with the same form to describe distributions that are negatively skewed, or bimodals. A combination of two-parameter distributions (say two log-normal distributions) requires the estimation of five parameters ($D_{1g}, D_{2g}, \sigma_1, \sigma_2, N_2/N_1$). At least five specific turbidity measurements at wavelengths far from each other are required for this estimation if the particles are in the submicrometer range. These parameters are expected to be very highly correlated and therefore the solution to be sensitive to experimental error. A good solution may be obtained in cases where the contribution of the distribution of the smaller particles to the overall specific turbidity is large; otherwise the large particles will always obscure the small particles.

Readers should keep in mind that in general, bimodal distributions (except those where the distance between the modal diameters of the two populations is large compared with the breadth of the two populations) are very difficult to resolve with most particle sizing methods. Using EM, for example, a large number of particles must be counted, sometimes at different magnifications in order to resolve the distributions successfully. DLS will usually result in distributions weighted towards larger particles. For bimodals where the distance of the two modal diameters is large compared with the breadth of the distributions, one can usually determine very successfully the particle sizes involved in the two populations (by EM and sometimes by DLS), but it is difficult to estimate the relative number of particles in the two populations. In such cases, if the diameters involved are known very accurately from EM ($D_1, D_2, \ldots, D_n$), then using a sufficient number of turbidity measurements one could estimate the relative number of particles ($f_1, f_2, \ldots, f_n$) (from Equations 31 and 39). Again, in order to obtain reasonable estimates, the small particles should weigh significantly and the distribution must be in an $(m, a)$ regime where specific turbidity measurements do not simply result in the same apparent diameters (otherwise all combinations resulting in the same average are possible solutions).

## 8 ON-LINE PARTICLE SIZE DETERMINATION USING TURBIDIMETRY

As early as 1973, Hamielec and Wright\textsuperscript{(84)} suggested using turbidimetry for on-line latex particle size determination. The configuration of a sampling device for on-line measurements of the PSD of poly(vinyl acetate) latexes using turbidimetry was suggested from that laboratory in 1976.\textsuperscript{(85)} On-line turbidity measurements in fully automated systems have been reported for poly(vinyl acetate) latexes by Kiparissides et al.\textsuperscript{(9,10)} and Zollars\textsuperscript{(11)} but no quantitative results from on-line particle size determination were reported by these workers. Haseler and Parkin\textsuperscript{(6)} used on-line turbidity measurements to monitor the growth of silver bromide in a ripening process. The ripening suspension was circulated continuously in an undiluted state through a thin cell.

In all of the applications mentioned above only turbidity was measured on-line. An experimental set-up to combine on-line determination of the particle volume fraction with on-line turbidity measurements, required for on-line specific turbidity measurements, was first suggested by Pollock.\textsuperscript{(86)} However, no results were reported on particle sizing, probably because he faced some problems with that set-up. A simulation for on-line latex PSD determination in continuous latex reactors was presented by Bradolin and Garcia-Rubio.\textsuperscript{(22)} Raphael and Rohani\textsuperscript{(22)} described a device that could be used on-line to measure the mean particle size in continuous precipitators or crystallizers. The solids concentration for this set-up is assumed to be known and no measurements on the particle volume fraction are taken on-line. This device was not tested on-line, however, for continuous production; the measurements reported were from spot samples. These samples were diluted in a vessel from which the diluted sample is pumped through the device and turbidity measurements are taken.

A serious disadvantage of some of the set-ups suggested for on-line latex particle size determination\textsuperscript{(9,10,11,22,86)} is that they require a continuous flow of diluted latex through the spectrophotometer. For specific turbidity measurements this means that a known amount of latex is continuously mixed with a known amount of diluent. Both the latex and diluent have to be pumped at constant flow rates. This in turn requires that a very small amount of latex be pumped at the exit of the reactor, at flow rates as low as 10 mL min\textsuperscript{−1}, for long periods of time. A peristaltic pump tried by Gossen\textsuperscript{(21)} for this set-up failed owing to coagulation of the latex due to high shear and chemical attack of the tube by the monomer. Other types of pumps tried in the same laboratory also failed.\textsuperscript{(23)} Another problem with continuous dilution of the latex is that an enormous amount of waste (very dilute latex) is created that requires treatment before disposal. This would cause problems in large-scale operations. The set-up suggested earlier from the same laboratory\textsuperscript{(85)} utilizes discrete sampling, but it has serious disadvantages.\textsuperscript{(23)}

A system suggested by Gossen\textsuperscript{(23,24)} measures both solids fraction and turbidity on-line, utilizes discrete sampling, is mechanically simple, has a short cycle time and high accuracy and it is set up such that thorough cleaning of the sampling element is performed after each sample. This sampling device was used for the on-line
application of specific turbidity to monitor particle growth during poly(vinyl acetate) production in continuous pilot-plant reactors. Samples were taken at discrete intervals of 5 min. Results were reported for a period of 10 h. The weight-average diameters estimated by turbidimetry showed excellent agreement with results from on-line DLS.\(^{(73)}\) These results, obtained by Gossen, represent the first published successful effort\(^{(24, 46, 73)}\) to combine on-line turbidity and density measurements and to monitor, on-line, weight-average diameters during latex production in pilot-scale reactors, in a fully automated manner. Details on the set-up and an error propagation analysis study can be found in Gossen.\(^{(23, 24)}\)

### 9 OTHER CONSIDERATIONS

#### 9.1 Choice of the Methods

It is a well-established perception in particle size analysis that there is no method which can be successfully utilized for every application. The effectiveness of each particle sizing method depends on the special needs applicable to each case. The selection of the method is a compromise between accuracy, cost, speed of analysis and robustness of the instrument in the plant or the laboratory environment. This section gives some examples that might help users decide if turbidimetry is suitable for their applications.

There are cases where an accurate estimate of the full PSD is required. In such cases the time required for analysis and the cost of the method are not usually an issue. Examples of such cases are the evaluation of a new process and the PSD of the new product, the study of the effects of various parameters on particle size in a set of designed experiments and the detailed study of a nucleation process where the PSD reflects the mechanisms that take place. For such cases more time and effort are usually spent than for routine particle size analysis and more than one particle sizing methods and/or alternative approaches to the same method are used. EM will provide measurements of the sizes involved in the distribution, and will give an indication of the type of the distribution (i.e. detect the presence of two populations, etc.). However, resolving the full \(f(D)\) with EM is a tedious task because a very large number of particles need to be photographed and counted from representative parts of the sample. Specific turbidity can be used to obtain a correct estimate of the weight-average diameter of submicrometer particles if the \((m, \alpha)\) regimes do not allow for the full PSD determination. If the \((m, \alpha)\) values allow for the full PSD determination, then regularization methods, where no fixed shape of the distribution is assumed, should be tried first. If these methods show that the shape is smooth and the log-normal assumption is sufficient, then this assumption can be used for subsequent routine analysis. DLS could also be used to corroborate the results for submicrometer particles. Alternatively, sedimentation field fractionation\(^{(87–89)}\) could be used; this method would be especially useful in cases where EM cannot be used either because the particles change size when they are measured dry or they need special treatment for EM measurements.

Sometimes only routine-type checks are needed and an average of the PSD or the log-normal assumption that will provide the main body of the distribution may be sufficient. Turbidimetry could be used as a fast, inexpensive technique for such applications.

In some cases only qualitative information is required, for example when studying qualitatively the effect of certain process parameters on the particle size. In such cases almost any technique can be utilized provided that the same quantity is followed and that this quantity is sensitive to small changes in the particle size. For example, specific turbidity can be used to follow a weight-average diameter or DLS to follow the intensity-average diameter. It is important that the same method be used to follow the same average throughout the study because, as discussed in the next section, different methods are theoretically directly related (and therefore are more sensitive) to different averages of the PSD. Other applications where the dependence of turbidity on particle size can be qualitatively exploited is to use turbidimetry as a detection system (as discussed in section 5.4) to detect the onset of agglomeration or reactor oscillations in latex production.

When the product is suspected to contain two populations of particles with different sizes (e.g. large and small particles due to a secondary nucleation), the small particle population will be clearly detected by EM or chromatographic (i.e. size separation) techniques. Size separation techniques are very powerful in detecting small-particle populations. If the contribution of the small particles to the overall turbidity is significant then the bimodal distribution can be resolved by turbidimetry using regularization algorithms (i.e. solving for PSD without assuming a fixed shape). Otherwise, specific turbidity will only provide the weight-average diameter for a bimodal suspension of submicrometer particles.

When choosing a method for on-line measurements, one must consider several factors: the type of process (batch or continuous), the purpose of the measurement (is it routine analysis where we are satisfied with an average size, or do we need accurate PSD determination), the required sampling frequency and analysis time of the method, the cost relative to the expected accuracy and the reliability and robustness of the method in the
plant environment. Turbidimetric methods utilize the fastest measurements (light is used as a probe). As a comparison, fractionation (separation) techniques cannot provide any estimate of the particle size or the PSD until the fractionation is completed.

It is clear that users must consider several factors before choosing the technique or a combination of techniques that are most suitable for their needs. This requires a good knowledge of the process, the product and the capabilities and limitations of the technique. Finally, quoting Groves, \(^{(90)}\) “the validity of the data need have no direct relation to the cost of instrumentation”.

9.2 Corroboration of Results

When another particle sizing method is used to corroborate results from turbidimetry, this second method must be chosen carefully. In general, when comparing results on the full PSD from different methods, the size range to which each of the methods is applicable, their resolution, the effects of errors on the estimated size and any assumptions introduced in each technique should be considered. This holds even when comparing results from two different turbidimetric techniques (i.e. turbidity ratio and specific turbidity). Erroneous conclusions may be obtained, as illustrated with the following examples.

The size range to which each of methods is applicable should be considered. Wales \(^{(58)}\) used particle size measurements from a Coulter Counter instrument to corroborate results from turbidimetry. Some discrepancies were observed between the two methods. From a detailed discussion \(^{(15)}\) of his work it became clear that in particle size regions where both Coulter Counter and turbidimetry are capable of providing a valid estimate of the PSD the two methods compared favorably. The discrepancies observed for suspensions with PSDs in the lower submicrometer range were not due to forward scattering as originally claimed. \(^{(58)}\) Rather, they were due to the fact that the Coulter Counter instrument could not detect very small particles (in the lower submicrometer region) and specific turbidity for the \((m, \alpha)\) values of those suspensions could only provide a correct \(D_m\) and not the full PSD. Discrepancies between turbidimetry and Coulter Counter results were also observed by Walstra. \(^{(16)}\) The Coulter Counter instrument should not be used to corroborate results from other techniques when dealing with distributions of small particle sizes (i.e. lower submicrometer particles) or PSD with tails of small particles.

Any assumptions involved in the methods should be considered. Some average diameters obtained by various techniques can be directly derived from the underlying theory whereas others depend on the validity of certain assumptions. Only quantities estimated directly from theory should be compared. For example, DLS measures an “average diameter” that corresponds to the mean diffusion coefficient of the suspension. With the assumption that the distribution of the diffusion coefficients is Gaussian, a PSD and its corresponding weight-average diameter can be calculated. However, although the estimated mean diffusion coefficient is correct, this weight-average diameter is not always equal to the true weight average of the suspension. In contrast, the weight average measured by turbidimetry is numerically close to the true weight average for most submicrometer suspensions. In another example, some DLS instruments utilize the Rayleigh–Gans approximation to convert distributions from an intensity basis to a weight basis. This approximation is not valid for very large particles and may cause serious errors in the calculation of the PSD on a weight basis for broad distributions or widely spaced bimodal distributions, even if the distribution estimated on an intensity basis is correct.

10 CONCLUSION

Turbidimetric particle sizing methods are experimentally simple, robust and have very good reproducibility and potential for on-line applications. They have been applied for the estimation of the PSD or an average size to a variety of particle suspensions (Table 1) with diameters ranging from 0.035 to 50 µm.

Specific turbidity can be used for reliable estimates of the average particle size and of the PSD of a suspension for a wider range of particle sizes than the turbidity ratio or the wavelength exponent techniques. This is because specific turbidity involves two independent measurements of the particle size via two different properties of the suspension (turbidity and solids volume fraction), whereas the other turbidimetric techniques are based on turbidity measurements only. Therefore, if the volume fraction of particles in the suspension can be measured, specific turbidity should be the turbidimetric technique of choice. The turbidity ratio or the wavelength exponent method should be used only if the particle volume fraction is unknown.

Because of the light scattering behavior, turbidimetric methods are not theoretically expected to provide information on the full PSD in many situations. In order to decide the type of information about the particle size (average size or full PSD) that can be extracted from any turbidimetric method, one must consider both the value of the refractive index ratio \((m)\) of the suspension and the \(\alpha\) values covered by the distribution. The same PSD that can be successfully estimated for one system may be impossible to estimate for another system with a different \(m\) value.

There are a few critical combinations of \((m, \alpha)\) values in turbidimetric analysis for nonabsorbing particles:
• suspensions of submicron particles and values of $m$ smaller than 1.15;
• suspensions with any value of $m$ and very small particles ($\alpha < 0.5$);
• suspensions of very large particles ($\alpha > 150$).

In these regimes, the turbidity ratio and the wavelength exponent method should be avoided and only specific turbidity should be used. If the particle volume fraction is not known, then for suspensions in the above regimes it is better to choose a sizing method other than turbidimetry. Furthermore, reliable information on the full PSD may be very difficult to obtain in the above regimes, by any turbidimetric technique, within experimental error. Specific turbidity, however, will give a very good estimate of meaningful averages of the PSD: the weight-average diameter in the first case (from the mean value of the apparent diameters at 400 and 600 nm), the turbidity-average diameter for suspensions of very small particles and the surface–volume-average diameter for suspensions of very large particles.

The particle size distribution and concentration of a colloidal dispersion can be determined by measuring its ultrasonic velocity and/or attenuation coefficient as a function of frequency and then using a suitable mathematical model to interpret the spectra. Ultrasonic spectroscopy can be used to analyze particle sizes between about 10 nm and 1000 µm, and is suitable for application to concentrated systems (often up to 50 wt%). This technique has considerable advantages over many alternative technologies because it can be applied to systems that are optically opaque without the need of any sample preparation.

1 INTRODUCTION

Ultrasonic spectroscopy utilizes measurements of the frequency dependence of the ultrasonic velocity and/or attenuation coefficient of colloidal dispersions to obtain information about the concentration and size distribution of colloidal particles. The velocity ($c$) at which an ultrasonic wave propagates through a particulate suspension, and the amount by which it is attenuated ($\alpha$), are governed by interactions between the ultrasonic wave and the particles, e.g. transmission, reflection, absorption, and scattering. Ultrasonic attenuation spectroscopy (UAS) is more commonly used than ultrasonic velocity spectroscopy (UVS), although both methods can provide similar information. Ultrasonic spectroscopy has advantages over many existing particle-sizing technologies because it is non-destructive and non-invasive, is capable of rapid measurements and can be used to characterize systems which are concentrated and optically opaque. Ultrasonic spectroscopy is sensitive to particles with radius between about 10 nm and 1000 µm. The maximum particle concentration which can be analyzed varies between about 10 and 50 wt% depending on the nature of the system. On the other hand, the technique is unsuitable for analyzing dilute suspensions, i.e. particle concentrations below about 1 wt%. The other major limitations of the technique are that air bubbles can interfere with measurements and that a large amount of information about the thermophysical properties of the component phases are needed to interpret ultrasonic spectra.

There are two major steps in the determination of particle size using ultrasonic spectroscopy: (i) measurement of the ultrasonic velocity and/or attenuation spectra of the colloidal dispersion and (ii) interpretation of the resulting spectra using a suitable theory. To obtain accurate measurements it is necessary to carry out both steps carefully.

2 MEASUREMENT TECHNIQUES

Determination of the particle size distribution of a colloidal dispersion relies on being able to measure the frequency dependence of the ultrasonic velocity and/or attenuation coefficient.\(^{(1-3)}\) The ultrasonic velocity is the distance the ultrasonic wave moves through the sample per unit time, whereas the attenuation coefficient is a measure of the decrease in the amplitude of the ultrasonic wave per unit distance traveled. The ultrasonic velocity can be determined by two different methods: (i) measuring the time, $t$ taken for a pulse of ultrasound to travel a known distance, $x$: $c = x/t$, or (ii) measuring the wavelength of an ultrasonic wave, $\lambda$, at a known frequency, $f$: $c = \lambda f$. The attenuation coefficient is determined by measuring the reduction in amplitude of an ultrasonic wave which has traveled a known distance through a material (Equation 1):

$$\alpha = -\frac{1}{x} \ln \frac{A_x}{A_0} \quad (1)$$

where $A_0$ is the initial amplitude of the ultrasonic wave ($x = 0$), and $A_x$ is the amplitude after it has traveled a distance $x$.

To cover a wide range of particle sizes it is necessary to measure the ultrasonic properties of a colloidal
dispersion over a wide range of frequencies. Commercial ultrasonic particle-sizing instruments typically make measurements over the range 1 to 200 MHz, which enables them to analyze particles between about 10 nm and 1000 µm in radius. This range can be extended by using custom-built techniques to carry out measurements at higher or lower frequencies.

The frequency dependence of the ultrasonic properties of colloidal dispersions can be determined using a number of different measurement principles. The major difference between them is the form in which the ultrasonic signal is applied to the sample, i.e. continuous wave, tone-burst or pulse (Figure 1). Nevertheless, the experimental apparatus used in the different techniques is usually fairly similar, consisting of a signal generator, a signal analyzer and a measurement cell (Figure 2).

2.1 Continuous Wave Techniques

Ultrasonic spectrometers which utilize continuous waves are usually referred to as interferometers. Interferometry of liquids can be carried out using two different types of experimental arrangement: fixed path length and variable path length (Figure 3).

2.1.1 Fixed Path Length Devices

In a fixed path length (or resonator) device, the sample to be analyzed is placed in a thermostated measurement cell between two parallel piezoelectric ultrasonic transducers: a transmitter and a receiver. A signal generator produces an electrical sinusoidal wave of appropriate frequency and amplitude. This wave is applied to the transmitter where it is converted into a sinusoidal ultrasonic wave that propagates into the sample. The ultrasonic wave undergoes multiple reflections between the two transducers which results in the formation of a stationary wave. The signal detected by the receiving transducer is amplified and relayed to a signal analyzer. The amplitude of the received signal goes through a series of maxima and minima, due to constructive and destructive interference, when the frequency of the ultrasonic wave is varied. The ultrasonic velocity and attenuation coefficient are determined by analyzing the resulting amplitude versus frequency spectra.

To a first approximation the attenuation per cycle (aλ) is given by Equation (2):

$$\alpha \lambda = \pi \frac{\Delta f_N}{f_N}$$

where $f_N$ is the central frequency of a maxima and $\Delta f_N$ is the width of the maxima at −3 dB, whilst the ultrasonic velocity is given by Equation (3):

$$c = 2d\Delta f$$

where $d$ is the path length of the measurement cell and $\Delta f$ is the frequency difference between the central frequencies of two successive maxima.
2.1.2 Variable Path Length Devices

In a variable path length device the sample to be analyzed is placed in a thermostated measurement cell which usually contains an ultrasonic transducer and a moveable reflector plate. A signal generator produces a sinusoidal electrical wave of the appropriate frequency and amplitude which is applied to the ultrasonic transducer where it is converted into a sinusoidal ultrasonic wave. The ultrasonic wave propagates into the sample and undergoes multiple reflections between the transducer and reflector plate which results in the formation of a standing wave. When the distance between the transducer and reflector plate is varied the amplitude of the signal received by the transducer goes through a series of maxima and minima because of constructive and destructive interference. The distance between successive maxima ($\Delta d$) is equal to half the ultrasonic wavelength of the sample, and so the ultrasonic velocity can be calculated:

$$c = \frac{d}{\Delta t} = \frac{d}{f \Delta d}.$$  

The amplitudes of the maxima decrease as the distance between the reflector plate and transducer is increased because of attenuation by the sample. The attenuation coefficient is determined from Equation (1) by measuring the amplitude of the maxima as a function of the separation between the reflector plate and transducer.

2.2 Pulse Techniques

Ultrasonic spectrometers that utilize pulse techniques may be operated in a pulse-echo or through-transmission mode. In the pulse-echo mode a single transducer is used to both transmit and receive the ultrasonic signal, whereas in the through-transmission mode separate transducers are used to transmit and receive the signal (Figure 4).

2.2.1 Through-transmission Techniques

The sample to be analyzed is placed in a thermostated measurement cell between two ultrasonic transducers: a transmitter and a receiver (Figure 4). The transmitting transducer produces a pulse of ultrasound which travels across the sample and is detected by the receiving transducer. The ultrasonic velocity and attenuation coefficient of the sample are determined by measuring the time-of-flight ($\Delta t$) and amplitude ($A$) of the ultrasonic pulse which has traveled across the sample. The ultrasonic velocity is equal to the length of the sample, $d$, divided by the time required to travel this distance: $c = d/\Delta t$. The attenuation coefficient is calculated by comparing the reduction in the amplitude of the pulse that has traveled through the sample with that of a pulse which has traveled through a calibration material: $\alpha_s = \alpha_c - \ln(A_s/A_c)/d$, where the subscripts $c$ and $s$ refer to the properties of the calibrant and sample, respectively. To obtain accurate attenuation measurements it is necessary to ensure that the measurement cell is well designed to minimize temperature fluctuations, reverberation of ultrasonic pulses in cell walls and transducers, diffraction effects and phase cancellation due to nonparallel walls.

The frequency dependence of the ultrasonic properties of a sample can be obtained using two different approaches: (i) the Fourier Transform (FT) method, and (ii) the tone-burst method. For both approaches, a pair of ultrasonic transducers is used which is capable of generating ultrasonic energy over a wide range of frequencies. These broad-band transducers contain piezoelectric crystals whose oscillation is highly damped by attaching a backing material to the crystal.

In the FT method, a signal generator is used which is capable of producing a broad-band electrical pulse which contains a wide range of frequencies. This pulse is applied to the transmitting transducer where it is converted into a broad-band ultrasonic pulse. After this pulse has traveled through the sample it is detected by the receiving transducer, and then digitized and stored. The frequency dependence of the magnitude and phase of the pulse are determined using a FT technique. The ultrasonic velocity is then determined from the phase, whilst the attenuation coefficient is determined from the magnitude. To cover the whole frequency range it is often necessary to use two or three pairs of broad-band transducers.
PARTICLE SIZE ANALYSIS

with different central frequencies. Ultrasonic velocity and attenuation spectra are acquired much more rapidly using FT pulse techniques than continuous-wave techniques. This is because the whole of the frequency range is measured by propagating a pulse through the sample, rather than having to make measurements separately at each individual frequency.

In the tone-burst technique, a signal generator is used which is capable of generating tone-burst pulses over the required frequency range. A “tone-burst” is a single pulse which contains a number of cycles of ultrasound at a fixed frequency (Figure 1). A tone-burst pulse of a particular frequency is applied to the transmitter, and then the magnitude and phase of the tone-burst pulse that travels through the sample and is detected by the receiver are measured. The ultrasonic attenuation coefficient is determined by measuring the amplitude of the received signal, whilst the ultrasonic velocity is determined by measuring the change in the phase of the received signal. An ultrasonic spectrum is acquired by repeating this process for a number of frequencies. Because measurements are carried out separately at each frequency, this approach is more time-consuming and laborious than the FT method.

2.2.2 Pulse-echo Techniques

The frequency-dependent ultrasonic properties of a sample are measured in a very similar fashion as in the through-transmission technique, except that a single transducer is used to both transmit and receive the ultrasonic pulses (Figure 4). The ultrasonic transducer generates a pulse of ultrasound which travels across the sample, is reflected from the back wall of the measurement cell, travels back through the sample, and is then detected by the same transducer. The velocity and attenuation coefficient are calculated in exactly the same manner as described for the through-transmission technique, expect that the pulse has now traveled a distance $2d$ rather than $d$.

To obtain accurate and reliable measurements it is important to take extreme care in designing and manufacturing measurement cells, for all types of ultrasonic technique. Some of the most important factors to consider are nonparallelism of surfaces, imperfect reflection at boundaries, reverberations in cell walls, temperature fluctuations and diffraction losses.

3 PARTICLE-ULTRASONIC WAVE INTERACTIONS

A knowledge of the physical basis of the various forms of interaction between ultrasonic waves and particles is necessary to understand how ultrasound can be used to measure particle size. The four most important types of interaction between an ultrasonic wave and a colloidal dispersion are listed below.

3.1 Intrinsic Absorption

Each of the individual component phases in a colloidal suspension absorbs ultrasound as a result of classical (viscous and thermal) and relaxation loss mechanisms. These losses are determined by the composition of the suspension, rather than by its microstructure. The magnitude of these losses can be calculated by measuring the ultrasonic absorption coefficients of the individual components.

3.2 Visco-inertial Dissipation Losses

In the presence of an ultrasonic wave a particle oscillates backwards and forwards because it has a different density to that of the surrounding liquid. This oscillation is damped by the viscosity of the surrounding liquid, which causes some of the ultrasonic energy to be converted to heat, and therefore leads to a reduction in the amplitude of the ultrasonic wave. The magnitude of these visco-inertial losses increases as the density difference between the droplet and surrounding liquid increases. Visco-inertial dissipation losses depend on the size of the droplets in a colloidal suspension.

3.3 Thermal Dissipation Losses

In the presence of an ultrasonic wave the temperature of a particle periodically increases and decreases relative to that of the surrounding liquid because of differences in the thermal properties of the continuous and disperse phases. The temperature gradient which arises at the particle surface causes a net flow of heat out of the droplet, which leads to a reduction in the amplitude of the ultrasonic wave, i.e. some of the energy initially stored in the ultrasonic wave is converted to heat. The magnitude of these losses is governed by the difference in thermal properties between the droplet and the surrounding liquid, e.g. thermal expansion coefficient, specific heat capacity and thermal conductivity. Thermal dissipation losses depend on the size of the droplets in a colloidal suspension.

3.4 Scattering Losses

The pulsation and oscillation of a particle in the presence of an ultrasonic wave causes the generation of secondary ultrasonic waves by the particle. Thus some of the ultrasonic energy associated with the incident wave is redirected into different directions, and an increase in
the attenuation coefficient may be detected. Scattering losses are usually negligible in the long wavelength limit \((r \ll \lambda)\), but become dominant when the particle size is of the same order of magnitude as the ultrasonic wavelength. Scattering losses depend on the size of the droplets in a colloidal suspension.

To a first approximation, the overall attenuation coefficient of a colloidal suspension can be considered to be the sum of these various contributions (although in reality some of these mechanisms are coupled to each other). In most suspensions, one or two of the above mechanisms usually dominate the overall attenuation in a particular frequency range. At relatively low frequencies, the visco-inertial and thermal loss mechanisms usually dominate, but at higher frequencies the intrinsic absorption and scattering losses usually dominate.

### 4 ULTRASONIC SCATTERING THEORY

Once the ultrasonic velocity and/or attenuation spectra of an emulsion have been measured it is necessary to convert them into a particle size distribution using an appropriate theory. Theories are based on a mathematical treatment of the physical processes that occur when an ultrasonic wave propagates through an ensemble of particles suspended in a fluid\(^{(1-3)}\). One of the most comprehensive models (Equation 4) is based on multiple scattering theory\(^{(13)}\).

\[
\left( \frac{K}{k_i} \right)^2 = 1 + \frac{4\pi N f(0)}{k_i^2} + \frac{4\pi^2 N^2}{k_i^2} (f^2(0) - f^2(\pi)) \quad (4)
\]

where \(f(0)\) and \(f(\pi)\) are the scattering amplitudes of the individual droplets (Equations 5 and 6):

\[
f(0) = \frac{1}{ik_i^2} \sum_{n=0}^{\infty} (2n+1) A_n \quad (5)
\]

\[
f(\pi) = \frac{1}{ik_i^2} \sum_{n=0}^{\infty} (-1)^n (2n+1) A_n \quad (6)
\]

Here \(K(=w/c_S + i\alpha_S)\) is the complex propagation constant, \(c_S\) is the ultrasonic velocity and \(\alpha_S\) is the attenuation coefficient of the colloidal suspension. \(k_i\) is the complex propagation constant of the continuous phase \((=w/c_1 + i\alpha_1)\), \(\phi\) is the disperse phase volume fraction, \(w(=2\pi f)\) is the angular frequency \(f\) is the frequency, \(i = (-1)^{1/2}\), and \(r\) is the droplet radius. The \(A_n\) terms are the scattering coefficients of the various types of waves scattered from the individual droplets, e.g. monopole \((A_0)\), dipole \((A_1)\), quadrupole \((A_2)\) etc.

Approaches for calculating the scattering coefficients of both fluid and solid particles are available in the literature\(^{(14,15)}\). The most rigorous approach calculates the \(A_n\) terms by solving a series of \(6 \times 6\) complex linear simultaneous equations at each value of \(n\), although simpler analytical expressions are available in the long wavelength limit\(^{(14,15)}\). The values of the scattering coefficients depend on the relative thermophysical properties of the component phases, the ultrasonic frequency used and the size of the emulsion droplets. The terms containing \(\phi\) in Equation (4) describe single scattering effects, whilst the terms containing \(\phi^2\) describe multiple scattering effects. Multiple scattering becomes increasingly important as the concentration of droplets in a colloidal suspension increases.

For a colloidal suspension containing polydisperse particles the above equation must be modified (Equation 7):

\[
\left( \frac{K}{k_1} \right)^2 = 1 + \frac{4\pi}{k_1^2} \sum_j N_f j f_j(0) + \frac{4\pi^2}{k_1^2} \sum_j N_{f_j} f_j^2(0) - f_j^2(\pi) \quad (7)
\]

where the subscript \(j\) refers to the property with droplet size \(r_j\). This equation can be used to relate the ultrasonic properties of a colloidal suspension (velocity and attenuation coefficient) to its thermophysical properties, composition \((\phi)\) and particle size distribution.

Recently, it has been shown that the above theory must be modified to take into account interactions due to overlap of viscous\(^{(16)}\) and thermal waves\(^{(17)}\) generated by the particles. These interactions cause large deviations between the classical multiple scattering theory and experimental measurements at low ultrasonic frequencies, small droplet sizes and high droplet concentrations.

### 5 INTERPRETATION OF ULTRASONIC SPECTRA

To determine the particle size distribution of a colloidal dispersion one usually measures its ultrasonic velocity and/or attenuation coefficient as a function of frequency. The particle size distribution is then determined by finding the droplet size distribution that gives the best fit between the predictions of the ultrasonic scattering theory and the experimental ultrasonic spectra\(^{(1,2)}\). There are two approaches to solving this inverse scattering problem: model-independent inversion and model-dependent inversion. In the model-dependent inversion method it is assumed that the particle size distribution follows some common form which can simply be modeled mathematically, e.g. log-normal (Equation 8).

\[
P(r) = \frac{1}{x_r \ln \sigma_g \sqrt{2\pi}} \exp \left( -\frac{\ln^2 \sigma_g}{2} \right) \exp \left( \frac{[\ln r - \ln x_r]^2}{2\ln^2 \sigma_g} \right) \quad (8)
\]
where \( P(r) \) is the probability of having a particle of radius \( r \), \( x_g \) is the geometric mean of the radius and \( \sigma_g \) is the standard deviation of the geometric mean. The droplet size distribution can then be characterized by only two parameters: \( x_g \) and \( \sigma_g \). The geometric mean and standard deviation which give the best agreement between the measured and predicted ultrasonic spectra are found by a least squares analysis. Most commercial ultrasonic instruments assume that the particle size distribution follows either a monomodal or bimodal log-normal distribution.

In the model-independent analysis no a priori assumption is made about the form of the particle size distribution. Although this method is scientifically more satisfactory, because many suspensions do not have particle size distributions which can be described by simple mathematical expressions, it is extremely time-consuming to compute. In addition, there are sometimes situations where a number of different particle size distributions give an equally good agreement between theory and experiment and it is not possible to decide which is correct.

6 APPLICATIONS

The ability of ultrasonic spectroscopy to determine the particle size distribution of colloidal suspensions has been demonstrated by many workers.\(^{(3,6,10,18-21)}\) Fully automated particle sizing instruments which utilize ultrasonic spectroscopy are available commercially. These instruments are capable of measuring both the disperse phase volume fraction and particle size distribution of colloidal suspensions in a few minutes. For certain systems, these instruments are capable of characterizing suspensions containing high particle concentrations (sometimes as high as 60%).

The attenuation spectra of a series of corn oil-in-water emulsions with different disperse phase volume fractions (1–50 vol%) are shown in Figure 5. The particle size distribution and droplet concentration measured by the ultrasonic technique are tabulated in Table 1. There is excellent agreement between the measured and actual volume fractions of the emulsions up to the highest droplet concentration. In addition, the mean particle diameter is relatively insensitive to droplet concentration, indicating that the ultrasonic technique is capable of analyzing this system over a wide range of concentrations without any sample preparation. Nevertheless, it should be noted that in systems where thermal or viscous overlap effects become important there may be quite large disagreements between the experimental data and the theories used to interpret them.\(^{(16,17)}\)

7 PERSPECTIVE AND FUTURE DEVELOPMENTS

The ability of ultrasonic spectroscopy to characterize colloidal suspensions which are concentrated and optically opaque without the need for any form of sample preparation is extremely important for many applications. There are few other particle sizing technologies which are capable of analyzing this type of system and therefore it seems likely that the ultrasonic technique will find increasing applications in the future. One of the areas where the technique is most likely to be used is for the on-line determination of particle size distributions of colloidal suspensions during processing. The ultrasonic technique could be used to monitor the efficiency of a processing operation in real time that could lead to a major improvement in the manufacture of many colloidal-based materials, e.g. foods, pharmaceuticals, petrochemicals, agrochemicals and cosmetics.
Despite its many advantages over alternative technologies there are a number of technical issues that need to be addressed before the technique finds more widespread use:

1. The classical multiple scattering theory used to interpret ultrasonic measurements gives excellent agreement with experimental data for semi-dilute emulsions containing noninteracting droplets. Nevertheless, it needs to be extended so that it can be applied to more concentrated emulsions and to take into account the effects of droplet flocculation.

2. The interpretation of ultrasonic measurements requires knowledge of a number of the thermophysical properties of the disperse and continuous phases, which are often not readily available in the literature or are difficult to measure. It is therefore important to develop a database of the relevant thermophysical properties for the materials commonly found in colloidal suspensions.

3. The presence of small gas bubbles can obscure the signal from colloidal particles because of their ability to strongly scatter ultrasound. Strategies for overcoming this problem need to be developed, e.g. degassing the sample or making measurements at frequencies where the gas bubbles do not scatter significantly.

Velocimetry in Particle Size Analysis

Patrick V. Farrell
University of Wisconsin-Madison, Madison, USA

1 INTRODUCTION

A wide variety of physical situations call for measurement of particle or droplet velocities. In many cases, these measurements accompany size measurements, but in some cases particle size measurements are not necessary. This section will focus primarily on the velocity measurements, with some mention of systems which can acquire both size and velocity measurements. The intent is to introduce some of the more common methods in use for measurement of particle and droplet velocities. It is likely that some useful techniques will not be included, but this article may serve as a useful introduction to some of the techniques. In many cases, the measurement methods described are available as partial or complete systems from commercial vendors.

Measurement of particle or droplet velocity can be a challenging task both in acquiring data with appropriate characteristics and in interpreting the measurements so that accurate and appropriate conclusions can be drawn from the experiment. This article will outline some of the attributes of the particles (distributed phase) and the background fluid or continuous phase that should be considered in making measurements of particle or droplet velocities. I will also describe some of the most common current methods used to acquire such measurements. While some example applications will be included, inevitably many areas of interest will not be fully explored. Hopefully, readers will be able to use this introduction to aid in thinking about such measurements, and will feel capable of searching for applications in the open literature that are directly applicable to their areas of interest.

In the context of velocity measurements for particles and droplets, “particles” may strictly include a wide range of materials, with the common understanding that a “particle” is a solid or apparently solid-phase material suspended in a different phase (gas or liquid) field. Solid particles may exist in solid suspensions, but this combination will not be explicitly discussed in this article. Droplet velocity measurements, however, will be included. A “droplet” is considered to be a small amount of a liquid-phase substance suspended in a different liquid or a gas phase. Many of the methods and considerations in this article also apply for bubbles–gas phase suspended in liquid phase. In subsequent parts of this section, “particle” velocity measurements will refer to measurements of solid particles, droplets, or bubbles, unless otherwise specified.

Since particle or droplet motion usually involves a continuous phase different from the particle or droplet phase, two-phase or multiphase flow considerations are important in developing measurement systems for these types

Velocimetry in particle size analysis encompasses the range of issues and methods used to measure particle velocities consistent with particle size measurement systems. Particle size may be measured simultaneously or consecutively with the velocity measurements described in this article. This article will present some issues that should be considered in selection of a velocity measurement technique. Three examples of commonly used particle velocity methods will be discussed as illustrations of possible approaches. For each of these examples, a brief discussion of advantages and limitations of the methods will also be presented.
of flows.\(^1\) One of the most important considerations in a multiphase flow is the lack of continuity for the distributed phase (droplet or particle) of the flow. Whether particles or droplets, as discrete entities, they have a distinguishable, Lagrangian character. In many cases, this means that the appearance of particles or droplets at a specific place and time in a flow (aside from any vector or scalar characteristics) seems to be a random event with some statistical character. In contrast, the continuous phase (usually liquid or gas) is almost always present at any location at any time in the flow field (except when displaced by particle or droplet). While some measured characteristics of the continuous phase may appear to be random (like instantaneous velocity in a turbulent field) the presence of a velocity value is not. The discontinuous sampling for particles and droplets presents some difficulties in measurement and interpretation of measurements, which will be discussed in later sections of this article.

The type, quantity, and quality of velocity information sought for particles or droplets will vary with the application and the flow of interest. One useful initial distinction is whether the particle velocity field is of interest in its own right, or is intended to be a marker for another flow field, typically the continuous phase flow field. While particle measurement methods may be similar for these two, the type of information sought may differ considerably.

The kind of information sought about a particle or droplet velocity may include the velocity magnitude, direction, and some marker of time and space to indicate where and when the velocity sample was acquired. In many cases, the detailed spatial and temporal markers are not retained; instead, spatial information is recorded from the known sample volume location or the location of the particle velocity sampling, and temporal marking may be eliminated in favor of some statistical temporal moments (like mean velocity and root mean square (RMS) velocity). Since measurement methods and details may change depending on which of these quantities is needed, initial selection of the type of information sought can be an important step in developing or selecting a measurement system.

While the range of possible measurement methods is broad, the most commonly used particle velocity measurement techniques seem to fall into three major categories: optical LIDAR (Light Detection and Ranging) type methods which rely on Doppler shift of laser light; laser Doppler velocimetry (LDV) systems which also rely on Doppler effects but in a different configuration; and direct particle imaging systems. These three types of measurements, and some variations, will be emphasized throughout this article.

### 2 CLASSIFICATION OF FLOW TYPES

#### 2.1 Characteristics of Particle Flows for Velocity Measurements

In order to select velocity measurement methods that are well suited to the situation of interest, it may be useful to identify and describe some relevant parameters of the particles or droplets and some parameters of the flow field. In this section, some relevant particle parameters will be identified and typical ranges described. In the following section, relevant parameters of the continuous phase or mean flow field will be described.

Some particle characteristics that impact selection and use of velocity measurement methods are shown in Table 1, and will be discussed below. The range of “typical” values shown in Table 1 is primarily for illustration. It is quite likely that successful particle velocity measurements can be made beyond the cited range of each characteristic, but a range is cited to give readers an idea of the range encountered in experiments.

**Particle size** is one of the most important of the particle characteristics that affect what kind of velocity measurement could be made and the quality of the

</table>
resulting measurement. The size range of particles whose velocity can be measured is relatively large. In particular, if the velocity measurement does not require a parallel size measurement, quite small particle sizes can have velocities measured. As will be discussed in the following sections, particle size (along with some other parameters) affects the detectability of the particle, its ability to accelerate and decelerate in concert with the continuous phase, and even whether and how particles will distribute themselves throughout a flow. Some of these topics will be discussed in later sections of this article; for others, readers will be referred to resources addressing these issues.

Perhaps the second most limiting characteristic for particle velocity measurement is the number density of particles in the region of interest. In many applications, identifying the velocity of a single particle, not the average velocity of an aggregate of particles, is the goal. To the extent that a single particle cannot be “isolated” mechanically or optically, it may be difficult to tag a particular particle with a specific velocity value. In other flows, an average velocity for an aggregate (spatial average) of particles may be sought; if the number density is too low, some methods designed for this type of measurement may not work properly. Most of the particle velocity techniques that will be discussed have ranges of particle number density in which they will work best. Outside of these ranges, the results of the method may not prove satisfactory.

Particle material density is related to index of refraction of the particle as well as its ability (or lack thereof) to be neutrally buoyant in the distributed phase. For marker particles, an expectation is that particles follow the continuous phase to some limit, which usually includes minimum and maximum velocities and acceleration. For example, to follow low velocity continuous-phase flows, particles need to be nearly neutrally buoyant in the fluid, or else they will have gravitationally induced velocities unrelated to the continuous phase velocity. Even in high-velocity flows, particles and droplets may have slip velocities relative to the continuous phase for transient flows.\(^2\)

Particle shape affects the way in which a particle can or will follow a continuous-phase flow, as well as the way in which a particle will scatter light. As mentioned above, many of the particle velocity techniques currently in use depend on light scattering from particles. Nonspherical particles may scatter adequately for some velocity measurements, but present significant difficulties when accompanying sizing methods are used. Further, since many size and velocity methods, like phase Doppler interferometry (PDI) expect spherical particles, the velocities associated with nonspherical particles may be discarded, leading to shape-biased velocity statistics. Identifying scattered light signatures, if that is important, from randomly oriented nonspherical particles is likely to be very difficult.

The particle complex index of refraction (and its relation to the continuous-phase index of refraction) combines the refractive effect of change of index of refraction at the particle–fluid interface and the absorption characteristics of the particle. In general, index of refraction for a particle is temperature dependent, and for many materials is only known approximately. Since many particle velocity measurement methods are optically based, this optical parameter is frequently an important parameter affecting scattered signal strength and system signal-to-noise.

Surface finish and the chemical characteristics of the particles are also characteristics that can affect choice and implementation of methods. Surface finish is presumably an issue only for solid particles (or perhaps very large droplets and bubbles where the local surface tension and radius of curvature of the interface are not sufficient to produce a “smooth” interface). Chemical characteristics may include mostly practical considerations for material handling and disposal, although some characteristics (like fluorescence) can be used as part of the measurement method.

Mutability of the particle refers to whether the particle composition or phase will change under the conditions of the experiment. In some cases, this feature may be an disadvantage, for example when oil droplets are used as markers for a heated gas flow, and the markers vaporize leaving no particles to detect in the flow. In other cases, this mutability can be used to advantage. For example, a liquid like TiCl\(_4\) could be atomized into a fine spray in a gas flow with some water vapor in the gas. A chemical reaction of the TiCl\(_4\) with the water vapor produces TiO\(_2\) powder and HCl vapor. The TiO\(_2\) provides small markers for the flow; dispersing the TiCl\(_4\) as a liquid spray may provide better particle size control than dispersing the TiO\(_2\) powder itself.

In summary, in order to focus on a set of methods likely to be successful for measuring the velocity of a class of particles or droplets, identifying the range of expected particle characteristics is an important first step. When particles are intentionally seeded into a flow, the selection of seed may be revisited once a measurement method has been selected to optimize the combination of particle and method. For naturally occurring particles, careful characterization of the particle characteristics can help make a successful measurement with a minimum of trial-and-error.

2.2 Characteristics of Continuous Phase for Particle Velocity Measurements

As was the case for particle characteristics, certain characteristics of the continuous phase have a

</table>

significant impact on the success of particle measurement. Table 2 outlines some of the more common flow parameters that affect the choice of particle velocity measurement methods and the measurements themselves. Many of the general features of a particular experiment are embodied in the description of the continuous phase flow field characteristics. These features include the size of the region of interest, access to the region, and whether the general flow is expected to be steady or transient. Taken together, these features start to suggest whether some sort of instantaneous “snapshot” of the particle velocities everywhere in the flow field is needed, or sampling particle velocities at one location over time is sufficient, or if something in between is needed.

In Table 2, the size of the flow field represents the total spatial region of interest. For imaging systems, this may indicate the size of the object field that needs to be imaged. Access, in Table 2, refers to the range of locations in the flow field where a sample of the continuous and distributed phase velocity might be available. As most current particle velocity measurement systems are optical, access refers primarily to optical access. For some flows, the flow may be accessed or sampled at only a few locations, with a limited “field of view”. Other experiments may have fewer limitations, perhaps allowing optical access to a large portion of the flow field for much of the time of interest. These access constraints may be important in selecting and applying a velocity measurement system because the systems themselves require different levels of access.

Temporal variation of velocity and the scale and frequency of variation are indications of the flow characteristics of the continuous phase. Many flows have an unsteady or even turbulent character. Depending on the magnitude and frequency of the behavior, for many of these flows, a statistical representation of particle velocity may be most useful. Typical flow statistics of interest may include a mean velocity, a RMS velocity, and perhaps higher moments of the velocity. Flows may exhibit very little variation from a steady mean velocity or slowly varying mean velocity (i.e. small magnitude or very low-frequency variations), indicating a laminartype flow. Alternatively, the flow may be a transient turbulent flow with time-varying statistics (mean, RMS, moments). Estimating the temporal characteristic of the flow is quite useful in assessing what kind of measurement, what data rate, and what resulting statistics are desired. Flow repeatability is related to this transient character, since this characteristic, when present, makes a repeated measurement on different realizations of the flow possible. A nonrepeatable flow would not permit such a data combination without significant degradation to the resulting data set.

Spatial variation of the velocity is the estimate of whether data sampled in one region of the flow are representative of that region alone, or of some broader range of locations. In parallel with temporal variations, spatial variations of flow velocity can be very small to quite large, responding to the flow geometry as well as to the overall flow type and structure.

The complex index of refraction and fluid density are of interest on their own, but are even more important when compared with the distributed phase of particles or droplets. Similar particle and continuous phase densities may make particles more likely to follow the flow (neutrally buoyant), while similar indices of refraction may make particles more difficult to identify because of the refractive characteristics for optical measurement systems. While most particle velocity measurement methods do not require exact knowledge of the particle or fluid (continuous phase) index of refraction, signal levels are affected by the difference in index between the particle and fluid.

As for the particles, chemical characteristics may be of interest in the measurement itself, or may be part of the measurement system (as for fluorescence) or may be issues to handle for chemical handling and disposal.
3 FUNDAMENTAL CHARACTERISTICS OF MEASUREMENT METHODS

3.1 Particle Characteristics Useful for Velocity Measurements

Particle velocity measurements are based on a variety of measurable quantities. Currently, the most common particle velocity measurement methods employ optical or ultrasonic scattering of incident waves. Typically, a portion of a signal, scattered by the particle field, is collected and analyzed to estimate particle velocity. Of the many techniques available, optical techniques seem to be most widely used, and will be emphasized throughout this discussion. The methods used in extracting the information from the scattered or unscattered signal distinguish one particle velocity method from another. As a result of the information extraction and analysis methods, the resulting measurements acquire specific characteristics and limitations.

In some situations, it is useful to use some other particle-related signal source besides scattered light. One type of particle-related signal source, which has been used successfully, is particle or droplet fluorescence, in which a particle absorbs light of a certain wavelength and immediately emits light of a different, usually longer wavelength. Since the particle acts as a virtual light source for the emission wavelength, the variation of the signal with particle size, number density, and other characteristics is a little different than for signals from light scattering. Nevertheless, since scattering is the most common approach in use, we will look at light scattering in some detail.

Among many different specific particle features which are usable for velocity measurement, there are two that seem to be the most widely used. One of these is the particle location, provided by viewing or recording an image of the particle at a sequence of well-known times. The second quite different particle characteristic that is frequently used is the frequency of light scattered from a particle of interest. A common requirement for either of these optical methods is the ability to collect a sufficient amount of light from a particle at some time and location. Among the issues of interest in enabling collection to occur are the object signal level (actually signal-to-noise) of the particle, and the resolution of the illumination and imaging system. Issues affecting the signal level will be described briefly in this section, while resolution issues will be presented in the following section.

For optical particle velocity methods, the intensity of light scattered from a particle is usually calculated from Lorenz–Mie theory (LMT) for scattering of light from spherical particles. Van de Hulst\(^3\) presents the general LMT equations as well as some special cases (e.g. \(d < \lambda\), \(d = \lambda\), or \(d > \lambda\), where \(d\) is the particle diameter), although all examples assume uniform illumination. Other work\(^4\) has extended LMT to include nonuniform illumination, as might occur for illumination by a Gaussian cross-section intensity laser beam. To illustrate the effect of the important parameters in particle light scattering, the basic LMT will be briefly outlined. A more complete description of scattering as a generalized solution to a wave equation is shown in Equations (1) and (2).

\[
\Delta \psi + k^2 m^2 \psi = 0 \tag{1}
\]

\[
\psi_{ln} = \left\{ \frac{\cos \theta}{\sin \theta} \right\} P_n^{(\cos \theta)} \ln (mk\theta) \tag{2}
\]

where \(n \geq l \geq 0\), \(K = 2\pi/\lambda\), \(r\) is the radial distance from the center of the particle, \(z\) is the propagation direction of the beam, \(P_n^{(\cos \theta)}\) is a Legendre polynomial, and \(\ln (mk\theta)\) is a spherical Bessel function. The incident light is assumed to be linearly polarized.

The incident beams can be written (for the two solutions to the wave equation) as in Equations (3) and (4):

\[
u = e^{i\mathbf{\phi}} \cos \phi \sum_{n=1}^{\infty} (-i)^n \frac{2n + 1}{n(n + 1)} P_n^{(\cos \theta)} j_n(kr) \tag{3}
\]

\[
u = e^{i\mathbf{\phi}} \sin \phi \sum_{n=1}^{\infty} (-i)^n \frac{2n + 1}{n(n + 1)} P_n^{(\cos \theta)} j_n(kr) \tag{4}
\]

The field outside a sphere resulting from scattering from the sphere and the incident wave, is given by Equations (5) and (6):

\[
u = e^{i\mathbf{\phi}} \cos \phi \sum_{n=1}^{\infty} -a_n (-i)^n \frac{2n + 1}{n(n + 1)} P_n^{(\cos \theta)} h_n^{(2)}(kr) \tag{5}
\]

\[
u = e^{i\mathbf{\phi}} \sin \phi \sum_{n=1}^{\infty} -b_n (-i)^n \frac{2n + 1}{n(n + 1)} P_n^{(\cos \theta)} h_n^{(2)}(kr) \tag{6}
\]

where \(h_n^{(2)}(kr)\) is a spherical Bessel function of the second kind.

The coefficients \(a_n\) and \(b_n\) can be determined using Riccati–Bessel functions as in Equations (7–9)

\[
\psi_{n}(z) = zJ_n(z) \tag{7}
\]

\[
X_{n}(z) = -zN_n(z) \tag{8}
\]

\[
\epsilon_{n}(z) = zH_n^{(2)}(z) \tag{9}
\]

\[
a_n = \frac{\psi_{n}' (y) \psi_{n} (x) - m \psi_{n} (y) \psi_{n}' (x)}{\psi_{n} (y) \psi_{n} (x) - m \psi_{n} (y) \psi_{n}' (x)} \tag{10}
\]

\[
b_n = \frac{m \psi_{n}' (y) \psi_{n} (x) - \psi_{n} (y) \psi_{n}' (x)}{m \psi_{n} (y) \psi_{n} (x) - \psi_{n} (y) \psi_{n}' (x)} \tag{11}
\]

where \(x = ka/\lambda\), and \(y = mka\).

For a specific index of refraction particle, calculations of the relative scattered intensity as a function of particle size and scattering direction can be calculated from
Figure 1 Calculated Mie scatter for 0.5, 2, and 10 µm spherical particles \((m = 1.5 + 0)\) as a function of collection angle. The calculation uses the methods of Bohren and Huffman.\(^5\)

Figure 2 Calculated Mie scatter for forward scatter (collection from 0 to 4°) and back scatter (collection from 176 to 180°) as a function of particle size. The calculation uses the methods of Bohren and Huffman.\(^5\)

Equations (5–9). Sample results for such calculations are shown in Figures 1 and 2 for several particle sizes at a range of scattering angles. Figure 1 shows the variation of scattered intensity for uniformly illuminated 0.5-µm, 2-µm, and 10-µm particles, as a function of collection angle, calculated using the method described by Bohren and Huffman.\(^5\) Even with the apparently small difference in size between 0.5 µm and 2 µm, the scattered intensity values are very different at most of the scattering angles shown. At the forward scatter collection direction (0°) the 10-µm particle shows over 10^2 greater scattering intensity than the 2-µm particle, and about 10^4 greater than the 0.5-µm particle scattering intensity at this collection angle. In this calculation, individual angles are calculated separately; actual collected light signals may differ somewhat from the scattered intensities shown because the optical collection system collects over a finite solid angle and will integrate over some of the irregularities of the single particle scattering curves.

Figure 2 shows the variation of scattered light intensity with particle size for “forward scatter” and “back scatter” collection angles. For these calculations, scattered intensity was integrated over 4° about 178° (176° to 180°) for forward scatter, and over 4° about 2° (0° to 4°) for back scatter. The changes in signal level with particle size for either collection configuration are significant. In addition, the difference between forward and back scatter for a given particle size is evident. The calculations shown neglect some real behavior likely to be present in scattering situations, like nonuniform illumination, but they give some order-of-magnitude estimates for the impact of particle size and collection angle on signal strength.

Experimental measurements of particle scattering efficiency for different particles are available.\(^6,7\) An example of these measurements is shown in Figures 3 and 4. Figure 3 shows the minimum detectable particle diameter (defined as allowing >70% of the particles to be detected on film) in air as a function of the f number of the collection lens and the laser power used. Figure 4 shows the same basic results in a water flow. These measurements have focused on optical arrangements typical of LDV systems or particle imaging systems.\(^7\) In general, the experimental results are consistent with the scattered light calculations for dilute particle systems in which single-particle scatter of nearly spherical particles dominates.

Figure 3 Experimental minimum detectable particle diameter in air as a function of collection system f number and illuminating laser power. (Figure from Adrian and Yao\(^7\) and reproduced by permission of the Optical Society of America.)
Figure 4 Experimental minimum detectable particle diameter in water as a function of collection system f number and illuminating laser power. (Figure from Adrian and Yao [7] and reproduced by permission of the Optical Society of America.)

For some dense particle fields, the single particle scatter predicted by Van de Hulst and others is more the exception than the rule. In these systems the actual collected signal may differ considerably from the predictions due to multiple scattering of photons from not one, but several particles. There does not seem to be the same kind of detailed analysis of the high number density particle fields as for the low number density fields. The issue has been, and continues to be one of great interest because so many practical particle or droplet fields are, in fact, quite dense. These past studies include analysis of dense fields themselves, their effect on common measurement methods, and possible resulting biases in measurements made in these kinds of fields. More specific comments on the difficulties inherent in high number density particle fields will be included in the discussions of detailed techniques. The problems associated with these high particle number density fields vary somewhat depending on the choice of measurement method.

The results of either calculations or measurement for single particle scattering provide guidance in selecting parameters for experiments. Scattering from large particles is clearly much stronger than from smaller particles; “forward” scatter directions result in much higher signal levels than for other scattering directions. In general, diffraction is not included in these calculations, and for forward scatter, diffraction may dominate the refraction and reflection signals modeled by the LMT calculations.

Depending on the measurement scheme selected, different specific attributes of the scattered particle signal may be sought. Understanding of the general behavior of particle scattering may be a great help in designing a successful experimental method. Under some circumstances, calculating the relative or absolute scattering in a given direction for a particle size range may be useful, using the equations given by Van de Hulst or some more recent work suggesting how to speed up the recursive calculations involved. Some of this more recent work has also included nonuniform illumination (i.e. Gaussian beam profiles – a common occurrence in laser illumination of particles).

3.2 Temporal and Spatial Resolution Requirements and Limitations

A second major issue for most particle velocity measurement systems is accommodating the temporal and spatial resolution required to accurately evaluate the physical system. The range of spatial and temporal resolutions available from measurements is closely tied to the ability to capture a scattered signal with adequate signal-to-noise in a limited time over a prescribed volume. Currently, hardware limitations have a significant effect on the range of temporal and spatial resolutions achievable. Hardware and data “bandwidth” limitations often cause spatial and temporal resolution capabilities to be intertwined, not independent of one another.

There are many common choices for spatial and temporal resolution. For example:

- low spatial and low temporal resolution – as for measurement of a steady homogeneous particle field; particle velocity measurement might be spatially averaged over a volume of 10 m × 10 m × 10 m with a temporal resolution of 1 s (update rate);
- moderate spatial resolution, low temporal resolution – as for the measurement of a steady particle flow with spatial values desired every 1 cm in a 1 m × 2 m × 10 m volume; temporal resolution might be about 1 s;
- high spatial and temporal resolution – as for measurement of an unsteady, inhomogeneous flow with spatial values desired every 1 mm in a 100 mm × 100 mm × 100 mm volume; time constant of the flow is expected to be about 50 µs, requiring data rates of 40 kHz (2 × 20 kHz to satisfy Nyquist criterion) or greater.
Each of these measurements presents quite different spatial and temporal resolution requirements and will result in different selection of experimental parameters, if not in different experimental procedures altogether. Within any technique, a range of capabilities is possible with different experimental strategies or hardware. For the techniques most commonly used in particle velocity measurements, typical ranges are shown in Table 3.

In this table, “Spatial sample volume size” is intended to indicate the spatial volume over which measured particle values are averaged, producing one velocity vector for each specified volume of particles regardless of how many particles may be present in the volume. Clearly other values, both larger and smaller are possible with different selection of experimental parameters. The major point of Table 3 is to illustrate the differences among three common particle velocity measurement techniques in terms of spatial and temporal velocity value resolution. For example, a LDV (sometimes known as a laser Doppler anemometer or LDA) system usually has a relatively small sample volume and has the ability to sample particle velocities within that volume at quite high rates. However, LDV or LDA systems have no innate capability of providing multiple simultaneous samples at many different locations – although multiple systems can provide multiple sample volumes. In contrast, some direct imaging systems can sample at a great many locations within a flow simultaneously (via a two-dimensional image), but due to the difficulties of rapid, pulsed, illumination and rapid storage and transfer of images, most are not able to provide a temporal succession of images at a rate anywhere close to the sampling rate of the LDV system. Depending on the flow and type of information sought, either or both of these systems may produce useful information, but the choice of measurement system needs to be matched to the kind of information sought, bearing in mind the current limitations of each of the methods.

It should be noted that these methods need not be used exclusively, but can be used in complimentary ways. For example, a direct imaging method might be used to provide large-scale spatial data from a flow field and to provide data on spatial flow patterns in the flow field. An LDV system could be used to probe locations of particular interest to provide a temporal record of velocity values at a number of discrete locations.

New methods of particle velocity measurement are constantly being developed to provide capabilities not available with current systems or to adapt some current systems to new applications. For example, a recent combination of full-field particle imaging with Doppler shift measurement produces “global” Doppler velocimetry which looks like a high spatial resolution version of the single detector LIDAR type systems.

One unmentioned, to this point, but quite important issue in comparing different approaches to particle velocity measurement is the inherent dynamic range of velocity which can be measured, the accuracy with which a velocity can be measured, and the uncertainty in the measurement. These attributes are also significant in selecting an approach for velocity measurement, but the actual statistical values will vary with details of the application, including hardware and software used. Some discussion of these issues, and the ranges that may be possible, will appear in the sections specifically describing the most common implementations of the approaches outlined here.

### 3.3 Coupling Velocity and Particle Size Measurements

Throughout this discussion of particle velocity measurements, the possibility of obtaining simultaneous particle size and velocity measurements has been ignored. There are methods that combine one of the presented velocity measurement methods with a particle size measurement to produce simultaneous size and velocity measurement, and consequently size–velocity correlations. By far the most common commercial method for this kind of measurement is the phase Doppler method, here generically called PDI. This method relies on an LDV type system for velocity measurement and a phase-shift method for size analysis. Since particle size measurements are covered in a different entry in this volume, they will not be presented here. The velocity measurement portion of these systems is very similar to the LDV systems used in velocity-only measurements, so discussion of velocity-only measurements may be extended to the velocity part of PDI size and velocity measurements fairly easily.
A second set of methods for combined size and velocity measurements involves some of the direct imaging methods discussed below, combined with particle size evaluation from the images. As for the PDI systems, the velocity portion of these measurements is similar to direct imaging, velocity-only measurements. A major exception to this similarity is the requirement for accurate particle image sizing. For velocity and sizing, the imaging system must produce accurately sized particle images. As this is not strictly necessary for velocity-only measurements, in most cases this presents a much stricter requirement on the imaging and recording system than velocity-only systems require. These additional requirements will be discussed in the portion of this volume that focuses on particle sizing.

3.4 Biases and Uncertainties in Particle Velocity Measurements

Any measurement is likely to have some bias and uncertainty. For the methods described in this short overview, many of these biases have been studied extensively. Rather than repeat those evaluations, readers will be referred to reference works on the subject.\(^{(2,17)}\)

In general, biases for particle velocity measurement arise for a variety of reasons. The most notable biases are due to the limited ability of a sample of particle velocities to represent the entire ensemble of particle velocities in the flow, and the instrument characteristics that do not sample all particle sizes and velocities “fairly”. For example, in many flows particles exhibit a distribution of velocity magnitudes and directions. For a sample of particles streaming through a fixed control volume over a fixed period of time, the probability of high-velocity particles passing through the volume is higher than the probability of low-velocity particles. The resulting ensemble of particle velocities may not accurately represent the true distribution of velocities as high-velocity particles may be overrepresented. This particular “velocity bias” is well known in the LDV field and some corrections for the bias have been suggested.\(^{(2,17)}\)

Because of the complexity of obtaining any particle velocity values in some situations, it is tempting to assign any values obtained as representative of the entire particle field. Any method known to the author has some bias associated with it, whether that bias can be quantified and “corrected” or not. Users should try to recognize the range of biases likely in any application and, if it is not possible to reduce or correct for these characteristics, acknowledge their presence and likely influence on the resulting data and conclusions.

For approaches outlined in this article which rely on the ability to detect Doppler frequency shift in a light beam for measurement, the major difficulties arise in the separation of the shifted light frequency from the unshifted light frequency, and the association of the intensity of shifted light at a shift frequency with particle velocity. This topic has been presented in several papers discussing LIDAR applications and similar Doppler shift measurements.\(^{(18)}\)

For LDV systems, measurement bias has also been a consideration almost since the technique was developed. While corrections for some of the known biases inherent in the method have been developed,\(^{(19)}\) for other biases (like a nonrepresentative sample), no real correction is available without significant assumptions about the overall character of the particle and continuous phase flow.

Direct imaging approaches have also been examined in some cases for measurement biases, and a series of guidelines have been suggested to minimize the impact of some of these biases.\(^{(20,21)}\) Even so, because of the complexity of the experimental technique, direct imaging approaches remain susceptible to biases in the measurement, which are not always recognized.

4 APPLICATIONS OF MEASUREMENT APPROACHES

4.1 Frequency Shift (Doppler) Methods

Frequency shift or Doppler shift methods rely on the frequency shift of light scattered from a particle for measurement of particle velocity. Successful implementation implies a well-characterized linewidth for the incident light, and some knowledge of the scattering characteristics of the particle or particles. Two implementations of Doppler shift methods will be outlined in this section.

The first of these is a LIDAR system designed for measurement of atmospheric velocities by sampling particle (aerosol) or molecular velocities. The second implementation of a Doppler shift approach is LDV. This method is commonly used to measure particle or droplet velocities and particle size in a PDI system or separately in a velocity-only system such as an LDV or LDA system.

In Doppler shift measurement systems, a well-characterized, narrow linewidth light source (laser) is used to illuminate one or more particles. Scattered light is collected from the particles in the field. Equation (10) shows that the frequency of the scattered light is shifted by the vector velocity of the particles in a direction related to the illumination direction and the collection direction,

\[
\tilde{f_D} = \frac{\tilde{u}}{\lambda} (\tilde{r} - \tilde{S})
\]  

(10)

where \(\tilde{r}\) a unit vector in the direction of the collection optics, and \(\tilde{S}\) is the Poynting vector of the incident light.
Equation (11) shows that for typical values of $\bar{u}$ (50 m s$^{-1}$) and $\lambda$ (532 nm), particles traveling toward the incoming beam, and the scattered light collected back along the direction of illumination,

$$f_D = \frac{\bar{u}}{\lambda} (\bar{f} - \bar{S}) = \frac{50 \text{ m s}^{-1}}{532 \text{ nm}} = 93.9 \text{ MHz}$$

(11)

This represents a large absolute frequency, but it is relatively small compared with the base frequency of light at 532 nm (~5.6 × 10$^{14}$ Hz) or 1.67 × 10$^{-5}$ % of the mean frequency. This Doppler shift frequency is clearly very small relative to the light frequency, which can make the shift difficult to detect directly. LIDAR systems typically make this measurement, using several different kinds of set-ups and filters to measure the frequency of the Doppler shift. LDV systems usually use a dual-beam arrangement, discussed below, which makes the electronic signals corresponding to the Doppler shift easier to detect.

### 4.1.1 Light Detection and Ranging Systems

For measurement of particle velocity, frequently as a marker for wind velocity, LIDAR systems have been developed which are capable of providing velocity data at long ranges (>10 km) from the source/detector. In general, these systems aim to gather the velocity of particles in some region illuminated by a laser beam, and measure an average velocity for the particles in the region. Depending on the specific technique, the particles may be droplets, dust, or molecules themselves. Figure 5 shows a comparison of the relative Doppler shift frequency widths from aerosol (particle) scatter and from molecular scatter.

Most of these systems rely on a Doppler shift of the laser frequency and subsequent determination of the magnitude and direction (relative to the laser line) of the shift to determine particle velocity. These systems are usually divided into coherent$^{(22)}$ and incoherent$^{(23–28)}$ systems, depending on the strategy used for detecting the Doppler shift. A schematic of a typical LIDAR system for velocity measurement is shown in Figure 6. In this method, a laser, usually a pulsed laser like a Nd:YAG (neodymium:yttrium aluminum garnet) (10–1000 pps, $\lambda = 1064$ or 532 nm), is the light source. A pulse of light leaves the laser and optical system, pointing at a region of interest. Scattering from airborne particles, like dust or water droplets, scatters laser light back along the path of the laser. An optical system collects the scattered light and focuses it onto a detector. The optical filtering of the collected scattered light is the key to this method. The frequency of the light has been Doppler shifted and perhaps broadened by the motion of the scatterers. The frequency of the Doppler shift is directly related to the particle velocity (towards or away from the source and detector).

Detection of the Doppler shift in these systems differs depending on whether the system is designed as “coherent” or “incoherent”. For the coherent case, where the collected light is presumably sufficiently coherent that optical interference is possible, optical heterodyne or homodyne processes using the backscattered light and a reference beam are used. Typical examples$^{(22)}$ use a CO$_2$ (10.6 µm) or Nd: YAG (1.064 µm) laser as a probe beam, and a stabilized version of the same laser frequency (homodyne) or slightly shifted (heterodyne) mixed with the scattered signal at the detector. The mixing of the two lasers at the detector allows the slightly shifted light returning from the sample volume to interfere with the unshifted light from the reference laser. The resulting signal at the detector will exhibit, among other frequencies, a frequency of oscillation corresponding to the difference between the return beam frequency and the reference beam frequency. The pulse delay from the outgoing beam to the return beam gives the range of the sample (distance out and back) and the frequency detected is related to the velocity parallel to the sample and return beams.

Incoherent systems rely on frequency separation of the laser frequency from the Doppler shift frequency by wavelength filtering. Two different approaches use either a high-resolution interferometer (Fabry-Perot) or a steep cut-off wavelength filter.$^{(23–28)}$ Normally colored glass filters or interference filters are not narrow enough, although argon ion laser sources (514 nm) have used an iodine cell to filter out the 514 nm line very effectively, producing a narrow bandwidth line filter which attenuates the laser line significantly.$^{(29)}$ These types of detection do not require mixing at the detector and can use less strictly controlled and coherent laser sources.

Other filtering strategies include “edge” filtering in which the cut-off edge of an optical filter is characterized
and used in the return signal from the LIDAR system with the calibration information to produce intensity values proportional to frequency, and therefore particle velocity. For each of these cases, the actual measurement is usually of particle velocity for airborne aerosols ($d_p > 1\, \mu m$). A sample of a system and results from an incoherent system are shown in Figures 6–8. In these figures, individual locations provided measurements of wind speed over time to produce a space–time profile (Figure 7) or a vertical profile (Figure 8).

Alternatively, LIDAR methods can be used with molecular scattering ($d_p < \lambda$ or $d_p < 1\, \mu m$) and get similar types of results, although the scattering intensities and linewidths are quite different for the case of molecular scattering as noted in Figure 4. An example of molecular scattering using an incoherent system is shown in the work by Abreu et al. It may be noted that for molecular scattering, since the particle size is much less than the wavelength of light, the type of scattering is called Rayleigh scattering. One evident characteristic of Rayleigh scattering is that the scattering cross-section varies as $1/\lambda^4$. Shorter wavelength sources therefore appear to be advantageous if molecules are the scattering target, and many newer LIDAR systems use second harmonic generated wavelengths of an Nd:YAG laser (at $\lambda = 532\, \text{nm}$) or the third harmonic of an Nd:YAG
(λ = 355 nm) to take advantage of the larger scattering cross-section at these shorter wavelengths.

4.1.2 Laser Doppler Velocimetry

LDV or LDA is among the most widely used particle or droplet velocity measurement techniques for single point measurement of particles. LDV has found applications in a wide range of situations from liquid to gaseous flows, for relatively dilute to fairly dense particle number densities, and for a wide variety of other relevant parameters.

A typical simple LDV system is shown in Figure 9. A laser source (usually a continuous-wave helium–neon, argon ion, or laser diode) is split into two parallel beams. The beams are focused to a single point, where particles are expected to appear. As a particle passes through the crossing volume in the plane of the crossing beams, photons are scattered simultaneously from each beam. From the geometry of the system, it may be evident that the photons scattered from beam 1, are frequency shifted (from Equation 11) as shown in Equation (12)

\[ f_{D1} = \frac{\bar{u}}{\lambda} (\bar{r}_1 - \bar{s}_1) \]  

Similarly, the photons from beam 2, are scattered by the particle with a frequency given by Equation (13)

\[ f_{D2} = \frac{\bar{u}}{\lambda} (\bar{r}_2 - \bar{s}_2) \]  

Scattered photons are collected on to a single point detector, typically a photomultiplier tube (PMT), and the resulting signal is processed to determine the frequencies present in the signal. Signal mixing of the coherent scattered light (amplitude addition) at the photocathode of the PMT results in frequencies given in Equation (14)

\[ f_{net} = (v + f_{D1}) \pm (v + f_{D2}) = 0 \]

or

\[ f_{net} = 2v + f_{D1} + f_{D2} \]  

Since the base laser frequency v is well beyond the high frequency limit of the PMT, only signals proportional to the Doppler shift, \( f_D \) fall within the bandwidth of the detector and are recognized. Using the previous definition of Doppler shift, Equation (15) gives

\[ f_{D1} = \frac{\bar{u}}{\lambda} (\bar{r}_1 - \bar{s}_1) \]

and

\[ f_{D2} = \frac{\bar{u}}{\lambda} (\bar{r}_2 - \bar{s}_2) \]  

the detected signal should look like

\[ f_D = f_{D1} + f_{D2} = -\frac{\bar{u}}{\lambda} (\bar{s}_2 - \bar{s}_1) \]

\[ \frac{2u_x \sin(\kappa/2)}{\lambda} = \frac{\bar{u}}{\delta} \]  

and

\[ \delta = \frac{\lambda}{2 \sin(\kappa/2)} \]  

where \( u_x \) indicates the velocity component in the plane containing the two laser beams, in a direction normal to the bisector of \( \kappa \).

Combining Equations (16) and (17) gives Equation (18)

\[ u_x = \frac{f_D \lambda}{2 \sin(\kappa/2)} \]  

where \( \kappa \) is the angle between the two incoming beams.

An alternative explanation for the operation of an LDV system, which is often offered, revolves around the formation of interference fringes at the point where the laser beams cross. A particle passing through the crossing region will scatter photons in the region of the crossing. The interference pattern fringe spacing is determined by the geometry of the LDV system. For initial parallel beam...
spacing $d_s$, with a lens focal length $f$, the crossing angle is given by Equation (19)

$$\tan \frac{\kappa}{2} = \frac{d_s}{2f} \approx \sin \frac{\kappa}{2}$$  \hspace{1cm} (19)

where the assumption of small $\kappa$ is made.

The resulting crossing volume, assuming Gaussian laser beam cross-sections is estimated to have a diameter $d = 4\lambda/(\pi d_s)$, and a length of $l = d/\tan(\kappa/2)$. The fringe spacing in the crossing region is given by Equation (20)

$$d_f = \frac{\lambda}{2 \sin(\kappa/2)}$$  \hspace{1cm} (20)

Since the time for a particle to pass between fringes is known from the optical signal, velocity is calculated from Equation (21)

$$u_x = \frac{d_l}{t_l} = \frac{f_0 \lambda}{2 \sin(\kappa/2)}$$  \hspace{1cm} (21)

The results of these two perspectives on LDV signals are the same, as seen in Equations (18) and (21). A typical LDV set-up might have conditions shown in Table 4.

While there are many different configurations for LDV systems, two important ones will be mentioned. For other configurations, some specialized to certain applications, the reader is referred to the references at the end of this section.

The first major modification to the simple geometry of the system described above, is the addition of some frequency-shifting to one or both of the laser beams. The goal of this shifting is to allow determination of velocity direction. In the simple system described above, particles with velocity components normal to the fringe pattern in the crossing volume are all evaluated as “positive” velocities, because they present an oscillating frequency at the output detector. Doppler shifts in frequency can be positive or negative about the laser frequency. Since the laser frequency appears as a time invariant signal, because its frequency is beyond the range of detectors, the Doppler shift frequency appears as positive or negative frequency shifts about the signal. Under these circumstances, positive and negative shifts appear the same. By frequency shifting one or both of the beams, an apparent motion of the crossing volume fringes at the frequency difference between the two beams superimposes a “bias” frequency on the fringe frequency from the scattered particles. The result is shown in Equation (22)

$$f_{det} = f_d + f_s$$  \hspace{1cm} (22)

where $f_s$ is the frequency shift imposed on the beams. For $f_s > f_d$ the resulting $f_{det}$ can now indicate positive Doppler shift at frequencies above $f_s$ and negative Doppler shift at frequencies below $f_s$. This frequency shift is usually accomplished using an acousto-optic modulator (also called a Bragg cell). A typical shifted and high pass

![Figure 10](image-url) - Typical LDV burst (with frequency shifting). This is a direct copy of an oscilloscope trace with a horizontal time base of 1 $\mu$s per division and a vertical gain of 20 mV per division.
filtered LDV signal is shown in Figure 10. This figure is taken directly from a digital oscilloscope. The vertical gain was set to 20 mV per division, and the sweep speed was 1 μs per division.

The second major change in configuration from the simple system outlined above is the use of fiber optics for delivery of the laser beams and transmission of the collected light from near the measurement volume to the detector. The use of optical fibers allows the laser and detector system to be mounted remotely from the experiment, with only a small number of optical elements near the actual sampling volume. With careful alignment, these systems can be made to operate as effectively as conventional delivery systems, and provide some system mounting and motion flexibility not easily available for conventional systems.\(^{2,30}\)

More recently, many other innovations in LDV configurations have been successfully demonstrated, including laser diodes for the illumination source, solid-state detectors for collection, and advanced electronics for signal detection and analysis.

Analyzing the scattered light from particles in the crossing volume quickly and accurately extracting the frequency information is a challenging problem in signal processing and analysis. For low noise signals (as in Figure 9), estimating the frequency of the high-frequency portion to calculate velocity is relatively straightforward. Historically, this has been handled by special purpose electronics.

In more challenging environments, such as ones with significant background noise from laser light scattering off windows, surfaces, etc. these systems struggle to find particle signals with peaks sufficiently above a filtered noise floor to provide accurate velocity values. Newer processors rely on fast Fourier transforms (FFTs) or digital Fourier transforms, or related autocorrelation methods to extract burst frequencies in the presence of higher levels of background noise. These systems are all commercially available, and details of their operation are left to their respective manufacturers.

The LDV system described provides one component of the particle velocity vector. To obtain the other two components, additional optics may be included essentially replicating the one-dimensional system in three dimensions. Usually, to allow for simultaneous measurement of two or three velocity components, different laser wavelengths are used for each component allowing easy separation of the different scattering signals.

One common application for LDV systems or other velocity measurement systems is to make useful measurements of particle turbulence characteristics. The particles may be serving either as a marker for the continuous flow or may be of interest in their own right. A velocity measurement system like an LDV system provides a series of “instantaneous” velocity samples over some collection time window. While turbulence data are contained in the instantaneous samples, the volume and character of this kind of data makes it awkward to use in describing the flow in a concise way. As a result, instantaneous velocity values are often decomposed using “Reynolds averaging” as in Equation (23)

\[
\bar{u}_i = \bar{u}_i + u'_i \tag{23}
\]

where \(u_i\) is the instantaneous velocity, \(\bar{u}_i\) is an average, either time average, as in Equation (24),

\[
\bar{u}_i = \frac{1}{\tau} \int_{t_0}^{t_f} u_i \, dt \tag{24}
\]

or an ensemble average, as in Equation (25)

\[
\bar{u}_i = \frac{1}{N} \sum_{j=1}^{N} u_{ij} \tag{25}
\]

Resulting data are often given as mean velocities (\(\bar{u}_i\)) and RMS (\(\sqrt{u_i^2}\)) values, normalized by an appropriate value.

A common extension to these basic velocity moments is the calculation of a timescale, called the “integral scale”, which is considered to be an indication of the timescales for large-scale turbulence in the flow. The integral timescale, \(L_i\), shown in Equation (27), is calculated from the autocorrelation coefficient, \(\rho(\tau)\), shown in Equation (26)

\[
\rho(\tau) = \frac{\bar{u}_i(t)u_i(t + \tau)}{\bar{u}_i(t)^2} \tag{26}
\]

\[
L_i = \int_0^\infty \rho(\tau) \, d\tau \tag{27}
\]

Results of mean velocities, RMS velocities, and integral timescales can be used for comparison with other flow conditions or other flows. It should be noted that the simple decomposition suggested by the Reynolds decomposition of Equation (22) is most useful for turbulent flows in which the mean flow is presumed to be steady, the flow is incompressible, and a “typical” turbulent energy cascade might be expected. For flows in which any of these assumptions is not valid, other more complex ways of defining a mean flow and the “turbulent” portion of the flow (and related turbulent characteristics) may be needed.\(^{31}\)

A sample of LDV results for a turbulent flow downstream of a rearward-facing step is shown in Figures 11, 12, and 13.\(^{35}\) The flow is a steady water channel flow over a step (an abrupt expansion). This is a common test problem for instrumentation and modeling systems as it involves a largely two-dimensional shear
1.0 0.0

Figure 11 Sample LDV results for water flow over a rearward-facing step. This figure shows mean axial velocity profiles at various distances downstream of the step. (Figure from Etheridge and Kemp\(^{31}\) and reprinted by permission of Cambridge University Press.)

\[ \frac{y}{H_s} = 1.0, 2.0, 3.0, 4.0 \]

\[ \frac{x}{H_s} = 1.0, 2.0, 3.0, 4.0 \]

\[ \frac{u}{u_{max}} \]

Figure 12 Sample LDV results for water flow over a rearward-facing step. This figure shows mean transverse velocity profiles at various distances downstream of the step. (Figure from Etheridge and Kemp\(^{31}\) and reprinted by permission of Cambridge University Press.)

\[ \frac{x}{H_s} = 0.0, 1.0, 2.0, 3.0 \]

\[ \frac{y}{H_s} = 1.0, 2.0, 3.0, 4.0 \]

\[ \frac{u}{u_{max}} \]

There are many other examples of LDV results in journal literature. Since application details may vary depending on specific application, further examples will be left to journals in the respective field of interest.

Before leaving this overview of LDV systems, some cautions regarding the constraints and biases in LDV measurements should be mentioned. As may be surmised, the LDV system expects only one particle to be in the crossing volume at any one time. If more than one particle is present, the actual frequency sampled is not likely to be related to the particle velocities in the form of Equation (21) unless the particles happen to have the same vector velocity in the plane of the illumination beams normal to the center line of the beams. Most signal processors go to great lengths to identify and discard data from multiple particles in the control volume. Clearly this presents a problem for very dense particle fields in which the likelihood of multiple scatterers in the control volume is high.

Since the actual time of appearance of a particle in the measurement volume is somewhat random, evaluation of LDV results is usually approached statistically. The underlying assumption (hope\(^{2}\)) is that the particles which did pass through the control volume, and whose signals passed all the processor tests, are representative of all “similar” particles in the flow field.

For LDV measurement systems, there are several major expected biases in the velocity signal. One of these arises from relative oversampling of the higher velocity particles, since they are more likely to pass through the control volume than lower velocity particles in a given sample time. A second bias is size biasing, in that larger particles can have an effectively larger detectable control volume than do smaller particles because of their larger scattering signal even in the weaker portions of the Gaussian probe beams. Note that simultaneous measurement of particle size and velocity allows users to access velocity–size correlations and assess the significance of this size bias. A third bias is velocity average biasing, in that standard time averages of particle velocities may overrepresent some samples because of the irregular arrival times (hence integration times) for particles in the system. There are methods to minimize the effects of these biases, and interested readers should consult appropriate references to understand the implications of these biases for the experiments of interest.\(^{12,17}\)

4.2 Direct Imaging Methods

Probably the most straightforward way of measuring particle velocity is to record an image of the particle of interest at a known time, and record a second image at some later time. An estimate of the displacement of the particle between the two images is available from the images, and combined with the known time between the two recordings, an average velocity can be calculated. Implementing this method in realistic particle or droplet
flows is frequently far from straightforward. Depending on many of the parameters of the flow and particles, different strategies may be needed to successfully acquire velocity data. In the end, direct imaging of particles for velocity measurements is not merely one technique, but a whole family of techniques for the range of situations of interest.

Many of the techniques used for direct imaging are relatively new, and several recent review papers provide a thorough background and reference list of recent fundamental and applied work in this field.\(^{(10,34-36)}\) In this section, some of the different approaches to direct imaging will be described and some of the choices that users need to make in selecting a specific technique will be indicated. In many cases, constraints on the techniques available for direct imaging are related to current hardware and software limitations. As new hardware and software with greater capabilities become available, some of the current limitations on direct imaging will change and the optimal system for a given application will likely change, too.

In the following paragraphs, I will outline some of the major features of a particle field which impact how a direct imaging experiment might be performed, and some of the
choices available to experimenters which also impact the type and quality of the results.

4.2.1 Particle Visibility

Recording a particle image requires an adequate number of photons to be scattered from a particle into the collection optics and system detector. The scattered intensity, as noted in an earlier section, is a function of particle size, index of refraction, shape, and collection direction and solid angle, among other things. As was discussed in the previous section, for particles near or greater than the wavelength of light to be used, LMT provides useful estimates of the spatial variation of scattered light intensity for various particle sizes and indexes for spherical particles. With a few exceptions, there are not many predictive results on scatter for nonspherical particles.

The range of particle visibilities is very large; for near-forward scatter directions, Mie scatter intensities vary approximately as $d^2$ (recall Figures 1–3, for example). In many polydisperse particle fields, a size distribution of an order of magnitude in particle diameter is likely (say 10–100µm), giving a range of scattering intensities of at least 1 : 100. This range is not particularly large for a size range, but may present some difficulties for image recording for limited dynamic range detectors like 8-bit (256 gray-level) charge-coupled device (CCD) cameras. For velocity measurement, accurate image size may not be essential or necessary as long as the image size is constant and relatively small. A wide range of particle visibilities presents the likelihood of size biasing the velocity statistics, in that the more visible larger particles are more likely to be seen and therefore will represent a higher proportion of the distribution of velocity samples than they represent in the actual particle system. If larger particles have different velocities from smaller particles (as is likely) the velocity mean and standard deviation will be affected by the sampling.

4.2.2 Particle Size

While particle size affects visibility, it also affects the minimum displacement that can be measured accurately for most of the analysis schemes, as this minimum displacement is some significant fraction of the particle size. In addition, for situations in which the particle is seeded into the flow as a marker, the size affects the ability of the particle to follow the continuous phase of the flow and provide an appropriate velocity value. This issue is the same one commonly considered for LDV measurements in flows.

4.2.3 Particle Density

Depending on the number of particles in an imaging volume and their distinguishability, different methods may be required to extract velocity data from a set of images. Particle density is clearly a function of the particle loading in the region of interest (i.e. particles cm$^{-3}$) but for imaging, the number of particles in the image volume may be more relevant. For dilute particle fields, individual particles can be identified and “tracked” from image to image, making a particle tracking velocimetry (PTV) system. For dense particle fields, obtaining an undistorted image of the particle region of interest may be difficult. In addition, as particles are unlikely to be distinguishable from one another in a sequence of images, an area average analysis for the particles falling in a region of the flow is usually used. Dense particle fields may cause significant attenuation of the illumination beam, leading to stronger scattering signals from some regions of the field than from others. Imaging through dense particle fields can also be somewhat problematic.

4.2.4 Particle Image Density

For imaging of particles, we normally assume that there will be little or no particle image overlap; actual experiments may impose a more severe requirement in that identifying particles in different images and “matching” the same particle between two images may be difficult if the particle image density is high. Actual particle density as well as the total particle volume collected in the image affect particle image density.

4.2.5 Particle Velocity

Since particle displacements are the actual measurement, expected particle velocities and the range of velocities will affect the choice of experimental parameters, like the time between images. This is because displacements that are quite small (less than a particle diameter) or quite large (>1/3 the “interrogation spot size”) may cause problems in measuring displacement.

4.2.6 Imaging System Characteristics

These characteristics include system magnification, resolution, aberrations, field size, working distance, and framing rate among others. Clearly, many of these characteristics are interrelated, but they affect the image quality, and the apparent particle size, displacement, and dynamic range. Commercial 35 mm format or medium format lenses of very high quality and moderate price are available for the optical imaging system. The specific characteristics of the selected imaging system along
with the detector characteristics will determine the system characteristics and aberrations. Typical choices of detectors range from conventional 35 mm cameras using high-contrast silver-halide film, to solid-state CCD detectors. Very high spatial resolution and/or large dynamic range systems typically operate at relatively slow speeds (imaging rates), while some lower resolution systems can operate at high imaging rates. These rates can range from less than one image s\(^{-1}\) (cooled 1000 pixel by 1000 pixel or more, by 16 bit, CCD slow scan) to 4500 images s\(^{-1}\) (256 pixel by 256 pixel CCD) to over 200,000 frames s\(^{-1}\) (drum camera with effective 16-mm image size on film). As new hardware is developed, particularly in the solid-state sensor area (CCD cameras), higher resolutions (e.g. 4 K pixel by 4 K pixel is now available), with large dynamic ranges (12 or 16 bit), at faster framing rates (>30 fps) will become available. Because of the trade-offs in the imaging system, clear system requirements are needed before specific hardware is selected. Conversely, access to state-of-the-art hardware may make the trade-offs in temporal and spatial resolution less limiting.

4.2.7 Illumination System Characteristics

Many issues regarding spatial and temporal resolution in the direct imaging system are affected by choice of illumination system and the associated illumination optics. A common choice for high-velocity particle imaging (say particle velocities > 10 m s\(^{-1}\)) is a pulsed laser, like a Nd:YAG (10 ns pulse length, 10–1000 Hz, \(\lambda = 532\) nm or 355 nm) which is formed into a thin (~500 \(\mu m\)) sheet to illuminate one plane of particles. For many experiments, the desired time between pulses is frequently so short that the standard repetition rate for the laser is too slow. This may require more than one laser synchronized together, or some clever modifications to the Q-switch circuitry to obtain two or more pulses with a time between pulses of the order of 10–100 \(\mu s\). For lower-velocity particles, a continuous-wave laser source may be satisfactory, since continuous-wave lasers can be shuttered mechanically or acousto-optically with microsecond precision.

Other requirements for the illumination source may include specific wavelengths for fluorescent particles (pumping an absorption band for the particle, then imaging a fluorescence wavelength to improve particle visibility), different pulse lengths (e.g. longer pulses for lower power density to conserve optics and windows), and polarization selection.

4.2.8 Interrogation or Analysis System

Once a pair or more of particle field images have been captured, evaluating the particle displacement between the two images can be done a variety of ways. As there is extensive literature on many aspects of this “interrogation” problem, readers are referred to the references, and only outlines of some strategies will be suggested here.

For relatively low particle density images, PTV analysis schemes can be used.\(^{36,39}\) These schemes usually rely on large particle-to-particle spacing allowing individual particles to be easily identified in each image and from image to image. Finding the particle velocity is a matter of tracking the particle images and calculating the displacements from image to image of the identified, “paired” particles. The result of this kind of interrogation of a set of images is a set of vectors for each particle pair, indicating velocity direction and magnitude. Since the method requires that there be relatively few particles in each image, only a few vectors result from each set of images. To build a spatially “complete” set of vectors that covers a significant portion of a volume of interest, a large number of replicates of the experiment may be required.

Data analysis methods for PTV focus on following particles from image to image, and ensuring that a single particle is “matched” with its corresponding image in other image frames. Two- and three-dimensional velocity vectors can be obtained with these methods.

For relatively high particle density images, PTV is difficult since the particles in each image cannot be easily “paired” with their images (i.e. all particles look alike). To overcome this identification problem, the solution sought is changed slightly. Rather than seeking a vector for each particle, we may be content to seek an average (or most probable) velocity or particle displacement in a small region of the flow. There are two major approaches to finding this local average particle displacement. They differ primarily in terms of what kind of image information is available. One approach, known as an autocorrelation approach, begins with both particle images (separated by some \(\Delta t\) superimposed), as might be the case for a double exposure on film or a solid-state detector. The second approach, known as the cross-correlation approach, begins with independent first and second images, as for consecutive images of the particle field.

Briefly, the autocorrelation approach selects a small region of the double exposure image to interrogate (interrogation region). Typical interrogation region sizes might be 1 mm in diameter or 1 mm by 1 mm square. The result of this data analysis will be an average particle velocity and direction over this interrogation spot size for all particles that lie within the spot and have a second image also lying within the spot. The autocorrelation of the interrogation spot with itself should provide information on the most probable displacement.
of particles in the region. The strongest correlation should be all particles with themselves, at zero displacement. The next strongest correlation of particle images in the spot should, we expect, correspond to the most frequent spacing between particles. Assuming the initial particle spacing in either of the two exposures is random, the most probable spacing (which is not random) should be the displacement that all particles underwent between the exposures of the first image and the second image. In general, the autocorrelation is given by Equation (28)

$$R(\vec{s}) = I(\vec{x})I(\vec{x} + \vec{s})\, d\vec{x}$$  \hspace{1cm} (28)

While this can be analytically calculated for each interrogation spot, it is usually more convenient to invoke the fact that for a function $f(x)$ with Fourier transform $F(s)$, $\int_\infty^\infty f^*(x)f(x + u)\, dx$ has a Fourier transform of $|F(s)|^2$. The utility of this theorem is that while calculating autocorrelations for many interrogation spots in an image may be rather slow, calculating Fourier transforms using the FFT may be significantly faster. As a result, most autocorrelation schemes for particle image velocimetry (PIV) calculate the autocorrelation using the following sequence:

1. Select interrogation spot
2. “snap” image of spot
3. two-dimensional FFT of image
4. $|F_{2D}(s)|^2$
5. $F_{2D}^*|F_{2D}(s)|^2$ (inverse two-dimensional FFT)
6. $R(\vec{s})$

Once the two-dimensional autocorrelation is acquired, the largest peak outside of the $\vec{s} \approx 0$ region should give the value corresponding to the average particle displacement. Suggestions for optimizing imaging, interrogation, and “peak finding” are given by Keane and Adrian.

Autocorrelations have been widely used in PIV. They are typically calculated digitally, but with an appropriate set-up may be “calculated” using an optical correlator. A major drawback of autocorrelation methods is that while velocity magnitude and direction can be obtained, the sense (positive or negative value of velocity) of the velocity cannot, because with double exposure images, it is not known which set of particle images corresponds to the “first” image, and which the “second”. When the two images are recorded separately, this information is available and can be used with cross-correlation to remove the 180° ambiguity of direction. The image separation may be accomplished by recording each of two images on separate pieces of film or separate solid-state detectors, or by tagging one set of images.

The most common tagging method is by color. For example, if two different color pulsed lasers are available, they may be synchronized such that one provides the illumination for the first set of particle images, and the second laser provides the illumination for the second set. If the images are recorded on a color sensitive detector or film, they may be later separated into a “first” and “second” image.

Performing a cross-correlation of particle images in a region of the total image with a similar region in the second image should produce a maximum cross-correlation value when the first image subset and the second subset are offset by the most probable displacement of the particles in the region. The cross-correlation typically used is defined in Equation (29)

$$\phi_{g}(m, n) = \sum_{k=K_{\min}}^{K_{\max}} \sum_{l=L_{\min}}^{L_{\max}} f(k, l)g(k + m, l + n)$$  \hspace{1cm} (29)

where $f(k, l)$ represents the intensity values at pixels locations $x_k$ and $y_l$ in the first of the two images, and $g(k, l)$ represents the intensity values at pixels locations $x_k$ and $y_l$ in the second of the two images. The correlation essentially searches for the offset $(m, n)$ of $g(k, l)$ with respect to $f(k, l)$ which produces the largest sum over the region. The offset corresponding to this peak is taken to be the average displacement of particle images in the region.

This process of cross-correlation continues with successive subregions of the image, sometimes with overlap of the image subsets, until the entire image has been sampled. As with autocorrelation methods, this calculation is usually performed using FFTs because the numerics are much faster than direct calculation of the cross-correlation. The sequence of operations is similar to that for autocorrelation, except two-dimensional-FFTs of each of $f(k, l)$ and $g(k, l)$ are needed at the beginning to produce the cross-correlation in Equation (28) after the last two-dimensional inverse fast Fourier transform (IFFT).

### 4.2.9 Particle Image Velocimetry Example

One example of direct imaging systems using particles as markers for flows will be shown. This example relates to the flow inside an internal combustion engine which is expected to have relatively high mean flow velocities (50 m s$^{-1}$) and high turbulence levels (>50%). The spatial scales of interest range from the full size of the flow chamber (100 mm $\times$ 100 mm $\times$ 100 mm) to smaller scales of turbulence (<1 mm). The mean flows are unsteady, varying at frequencies of up to about 1 kHz, with small-scale variations at 10 kHz or greater. Additionally, the
flow is not precisely repeatable (cycle-to-cycle variation), so replicates from different engine cycles have neither the same mean value nor the same turbulent statistics. The interest is to acquire velocity data with a reasonably high spatial resolution (1 mm $\times$ 1 mm $\times$ 1 mm) and temporal resolution (100 $\mu$s).

This application of PIV methods to engine flows is in general similar in concept to the previous PIV work by Adrian and engine work by Reuss et al. and Reeves et al. but differs in implementation and detail. The PIV method implemented here includes a data recording step with a double pulsed Nd:YAG laser as a light source, and an analysis step using an optical Fourier transform method to estimate particle displacement.

The particular flow of interest in this example was the gas flow near the periphery of a spray plume from a fuel injector. The spray chamber is a cylindrical chamber, about 150 mm in inner diameter, with the injector mounted at one end of the cylinder. The opposite end of the cylinder had a 100-mm fused silica window, and a small window was available at the periphery for introducing the laser light. The chamber is operated at room temperature, and is typically pressurized with argon to about 20 bar. Two frequency doubled Q-switched Nd:YAG lasers were used as illumination sources for the particle image recording. Balanced double pulses were obtained with a 6 ns pulse width and 20 $\mu$s pulse separation time. The laser beam was formed into a sheet and passed into the test section through the side so that the flow region of interest could be photographed through the large front window. The sheet thickness was about 0.5 mm and the beam height was about 25 mm. A 35 mm format camera was used to take the PIV photographs on Kodak Technical Pan 2415 film. TiO$_2$ was mixed with air in a particle generator and was mixed into the chamber with the argon.

A sample of the particle images and resulting autocorrelation based velocity vectors are shown in Figure 14. In this figure, the spray plume is clearly visible. Near the spray plume, small droplets may mix with the seed particles and the velocity in those regions is likely to be an average of the small droplet velocity and small seed particle velocities.

For turbulent flows, PIV or other direct imaging methods can provide detailed time-series data and resulting statistics, but with considerable difficulty. To produce a time series of velocity vectors at a point in a flow requires a statistically significant number of realizations (image pairs) at that location in the flow. Direct imaging systems do provide spatial information in each image, so spatial turbulence information is readily available, as opposed to temporal turbulent data single point systems like LDV provide. With spatially varying velocity vectors, instantaneous, spatially varying vorticity and strain rate values can be calculated. Using the spatial autocorrelation, in analogy to the temporal autocorrelation of Equations (25) and (26), an integral length scale could be calculated for the region of velocity vectors. For replicates of an experiment, these spatially varying turbulent quantities can be compiled into spatial and temporal values, using spatial and temporal averaging as appropriate to the application.

### 4.3 Recent Developments in Particle Image Velocimetry

Recently, direct imaging methods, and, in particular, PIV methods have expanded into three-dimensional velocity vector measurements. These systems usually employ two or more imaging systems to produce stereoscopic images or in a quite different approach, use holographic recording to allow for three-dimensional reconstruction of the image field.

The stereoscopic methods rely on the same basic imaging approaches outlined for the two-dimensional approaches discussed above, with some additional
complexity in imaging system set-up and subsequent data analysis to extract three-dimensional vectors from nonorthogonal data.\(^{(47)}\)

Holographic recording of particle images for reconstruction and evaluation of three-dimensional particle velocities is more complex than the stereoscopic approaches, but promises more than a single plane of three-dimensional vectors. These systems are still under development in research laboratories. Interested readers may find some discussion of holographic PIV in recent literature.\(^{(48–50)}\)

5 SUMMARY

The field of particle velocity measurement is very large, with a wide range of techniques available. In many cases, the most useful techniques turn out to be optical methods because of their accuracy, nonintrusive character, and ability to be applied remotely to a flow. In this article several characteristics of the particles (distributed phase) and the background fluid (continuous phase), which may be relevant in selecting a particle measurement method, have been outlined. Three of the most commonly used particle velocity measurement methods have been discussed. Readers interested in applying any of these are encouraged to take this section as an introduction and to dig deeper into the method and applications specific to their field of interest. Hopefully the introduction provided here and the short list of references will provide a good starting point from which potential users can further explore these and other techniques.

Separation and Analysis of Peptides and Proteins: Introduction

Christian Schöneich
University of Kansas, Lawrence, USA

Rapid advances in molecular biology, medicine, and the various genome projects will continue to demand new analytical methods and the improvement of existing techniques for the rapid and reliable analysis of peptides and proteins. Complex mixtures of peptides and proteins will be derived from cell lysates and body fluids. Several or all components of these mixtures shall be simultaneously characterized and quantified avoiding lengthy purification schemes for the individual components. Protein samples containing only one gene product may be quite heterogeneous depending on the degree and manifold of potential posttranslational modifications. Such modifications may be predictable based on known target sites for phosphorylation, sulfation, glycosylation, ubiquitinylation etc. However, proteins may also suffer additional, non-enzymatic, chemical modifications such as the deamidation of Asn (to L- and D-Asp, and L- and D-isoAsp), oxidation, β-elimination, and racemization. The latter processes are usually encountered during protein purification or long-time storage in pharmaceutical formulations. Some parameters controlling these non-enzymatic pathways have been established, according to which the most sensitive amino acids can be predicted. For example, ‘deamidation hot spots’ are located in flexible protein regions, predominantly when Asn is followed by a Gly residue. Nevertheless, there is considerable uncertainty with regard to the most sensitive positions affected by the other degradation pathways. For example, solvent exposure is an important parameter controlling Met oxidation in proteins by peroxides but, in some cases, the metal-catalyzed oxidation of these proteins targeted especially the least accessible regions which, however, contained several metal-binding residues in the vicinity of the affected Met residues. Diastereoselective product formation can add complexity to the analytical task. Asn deamidation can yield two enantiomers of each product, Asp and isoAsp (diastereomers, if these products are components of polypeptides). Met oxidation yields two MetSO diastereomers, Met-d-SO and Met-l-SO. γ-Irradiation of protein samples, important for pharmaceutical or food sterilization processes, can essentially racemize every amino acid at Cα. Finally, d-amino acids are an important component of peptide drugs designed for longer biological half lives. In the majority of the cases, the resolution of posttranslational modifications, including the respective enantiomers or diastereomers, can be achieved by one of several modes of high-performance liquid chromatography (HPLC) or capillary electrophoresis. Therefore, the present section includes the following articles on various modes of HPLC and capillary electrophoresis, important for the separation of peptides and proteins (see also the separate section on Liquid Chromatography): Reversed-phase High-performance Liquid Chromatography in Peptide and Protein Analysis; Hydrophilic-interaction Chromatography in Peptide and Protein Analysis; High-performance Liquid Chromatographic Separations and Equipment in Peptide and Protein Analysis; Miniaturization of; Capillary Electrophoresis of Peptides; Capillary Electrophoresis of Proteins and Glycoproteins; Capillary Electrophoresis in Peptide and Protein Analysis; Detection Modes for; Posttranslational Oxidative Modifications of Proteins. Often, proteins are subjected to proteolytic digestion, so that individual peptides and their potential modifications can be resolved (‘peptide mapping’). An important detail of the peptide mapping procedure is that, depending on the nature of the protein substrate, proteases may show nonspecific cleavage sites. Moreover, posttranslational modifications may lead to conformational changes of the affected proteins, which can affect the accessibility of cleavage sites. Thus, proteolytic digestion shall be carefully optimized and validated, and a chapter in this section introduces the reader to the various aspects of peptide mapping. Proteolytic Mapping. A separate article has been devoted entirely to the Peptide Diastereomers, Separation of. Mass spectrometry has advanced to become one of the most powerful tools in the analysis of peptides and proteins, largely due to the availability of soft ionization techniques such as electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI). The potential of mass spectrometry in the analysis of peptides and proteins is reviewed in three chapters in this volume: Capillary Electrophoresis/Mass Spectrometry in Peptide and Protein Analysis; High-performance Liquid Chromatography/Mass Spectrometry in Peptide and Protein Analysis; Matrix-assisted Laser Desorption/Ionization Mass Spectrometry in Peptide and Protein Analysis (for more details, see also the section Mass Spectrometry).

A fundamental task in protein biochemistry is the analysis of protein function, structure, and dynamics. A clean analysis of these parameters requires homogeneous protein samples, conveniently monitored by gel electrophoresis. Hence, we have included an article on Gel Electrophoresis in Protein and Peptide Analysis, together with articles on Protein Purification: Theoretical and Methodological Considerations [see also Proteins and Peptides Purification in Pharmaceuticals Analysis in Encyclopedia of Analytical Chemistry R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
the section *Pharmaceuticals and Drugs*] and the *Chromatography of Membrane Proteins and Lipoproteins*. The structural analysis of proteins requires one of several possible diffraction techniques, and the article *X-ray Crystallography of Biological Macromolecules*, introduces the reader to various aspects of protein crystallization and X-ray crystallography. Certain structural characteristics of peptides and protein such as, e.g. the extent of $\alpha$-helical and $\beta$-sheet conformation, can be quantitatively measured in solution by circular dichroism (CD) or Fourier transform infrared spectroscopy (FTIR). In this section, we have included an article on *Fourier Transform Infrared Spectroscopy in Peptide and Protein Analysis* [see also the section *Infrared Spectroscopy*] while an article on *Circular Dichroism in Analysis of Biomolecules* can be found in the section on *Biomolecules Analysis*. In particular, the FTIR experiments are also possible with solids, permitting the assessment of protein structural changes as a result of processing, e.g. freeze-drying. Protein structure and dynamics can be investigated by means of nuclear magnetic resonance (NMR), electron spin resonance (ESR) and fluorescence spectroscopy (where the latter two techniques require the covalent attachment of a spin or fluorescent label, respectively). In this section, the reader will find an article on *Electron Spin Resonance Spectroscopy Labeling in Peptide and Protein Analysis* and *Fluorescence Spectroscopy in Peptide and Protein Analysis*. The Nuclear Magnetic Resonance of Biomolecules and Glycoprotein Analysis: Using Nuclear Magnetic Resonance are covered in the sections on *Biomolecules Analysis and Carbohydrate Analysis*, respectively. More information on the NMR and ESR techniques can be found in the section *Nuclear Magnetic Resonance and Electron Spin Resonance Spectroscopy*. Many proteins function through the interaction with biomolecules such as other proteins, lipids, and/or (poly)nucleotides. Moreover, proteins play an active role in the binding and transport of many drugs. Therefore, we have included articles on *Protein–Oligonucleotide Interactions*, and *Protein–Drug Interactions*. A relatively novel technique to measure binding equilibria of proteins is surface plasmon resonance spectroscopy, covered in the article *Surface Plasmon Resonance Spectroscopy in Peptide and Protein Analysis*, which has the advantage that it can specifically measure on- and off-rates of the binding process. Finally, more insight into the dynamic processes of proteins may be obtained by molecular modeling techniques, which, however, strongly benefit from experimental data which can be used as constraints in order to speed up or bias the modeling process. This topic is covered in the article *Molecular Modeling in Peptide and Protein Analysis*.

Capillary Electrophoresis in Peptide and Protein Analysis, Detection Modes for

Paul L. Weber
Briar Cliff College, Sioux City, USA

1 INTRODUCTION

There are a variety of detection modes for CE and most of these are at least theoretically applicable to the detection of peptides and proteins. Of these detection methods, those which measure some universal property, such as refractive index or conductivity, are not generally useful. On the other hand, detection methods which depend on some property of the peptide or protein which allows differentiation from the background electrolyte and other sample components are of great utility. Thus, detectors sensitive to the absorption of UV/VIS electromagnetic radiation, Fl emission or EC activity are all used. Detection by MS is extremely powerful and can also function selectively by monitoring ions of a particular mass.

Some detection methods deserve special consideration since they can supply additional information about an analyte useful in its identification and characterization. MS and multiwavelength or scanning UV/VIS detectors provide such information. Obviously, the availability of commercial systems with such detectors and ease of use are of concern when selecting a method, prompting careful thought about the use of MS or EC detection.

The sensitivity provided by the detection method can be of paramount importance if the peptide or protein is present in low concentrations and cannot be concentrated sufficiently prior to analysis by off- or on-column techniques. This is particularly important for UV/VIS absorbance detection owing to the small optical pathlength encountered in CE. Derivatization of peptides or proteins to provide fluorescent tags provides increased sensitivity and, often, selectivity.

2 DIRECT DETECTION

2.1 Ultraviolet Detection

For underivatized samples, the most prevalent method of detection is ultraviolet (UV) absorbance detection in the 200–230 nm range, which is primarily due to the presence of amide groups necessarily present in all peptides and proteins. This is evidenced by an inspection of data presented in a recent handbook for protein analysis by capillary zone electrophoresis (CZE), micellar electrokinetic chromatography (MEKC) and capillary gel electrophoresis, 75 used detection wavelengths in the 200–230 nm range. Of the remainder, four used UV absorbance detection at other wavelengths while one used Fl detection. However, when capillary isoelectric focusing (CIEF) is used as the mode of CE separation, 10 out of 12 applications monitored absorption at 280 nm. Proteins
will show an absorption maximum at this wavelength owing to the presence of aromatic amino acids, and use of 280 nm detection avoids the problem of a high background absorption in the low-wavelength UV range due to the ampholytes utilized in the separation medium. Unfortunately, 280 nm detection results in a loss of sensitivity compared with detection near 215 nm and this requires higher concentrations of proteins to be used. This, in turn, may result in precipitation of focused proteins.\(^3\) If CIEF is used to analyze peptides that do not contain aromatic amino acid residues, an alternative, low-cost method which uses a universal detector that senses refractive index gradients can be employed and has been demonstrated to be effective in the analysis of tryptic digests of bovine and chicken cytochrome c.\(^4\) Of the 59 applications cited\(^5\) for the analysis of peptide hormones and model peptides, 47 used detection wavelengths in the 200–230 nm range. Of the remainder, four used UV absorption at other wavelengths, four used Fl, two EC, one MS and one refractive index detection methods.

UV detection systems, including multilength wavelength detectors, are commonly found in commercial CE systems and are relatively rugged and easy to use. Multiwavelength detectors such as scanning and photodiode-array detectors are used routinely because of certain advantages that they provide. For example, in a report on the refinement of a protein assay by CE for apolipoprotein A-I, a major indicator of arteriosclerosis, multiwavelength detection (Figure 1) indicated that a significant increase in the sensitivity of the method could be achieved by utilizing 195 nm detection rather than the commonly used 200–220 nm range.\(^6\)

The main problem associated with UV detection is the relatively low concentration sensitivity, typically exhibiting a limit of detection in the low-micromolar region for small peptides.\(^7\) Although the use of extended optical pathlength capillaries, available from commercial vendors, can increase sensitivity by an order of magnitude, further increases in sensitivity can be obtained most readily by using a different detection method.

### 2.2 Fluorescence Detection

Detection of fluorescent emission offers an inherently more sensitive method than UV absorption detection. Direct Fl detection of peptides and proteins is dependent on the presence of two amino acid residues, tryptophan and, to a lesser extent, tyrosine. Unfortunately, these are not particularly strong fluorophores and an even greater limitation is that their excitation range is in the 210–290 nm wavelength range, which is well outside the 488-nm argon-ion laser or the 594-nm helium–neon lasers used in commercial instruments. Nonetheless, in-house detection systems have been used for analysis with detection limits in the low-nanomolar range\(^8,9\) for peptide analysis. Even lower limits (200 pM) have been reached\(^10\) for selected peptides with high tryptophan content. Additionally, this detection method permits the acquisition of emission spectra, affording discrimination between peptides containing tryptophan and/or tyrosine.

In general, derivatization of peptide or protein with a fluorescent tag conducive to detection with commercial detectors is the preferred method for sensitive detection. Direct Fl detection is probably confined to use for samples containing tryptophan or tyrosine residues where the additional demands inherent in the derivatization process, such as sample handling, dilution of sample and background Fl introduced by the derivatizing reagent, are undesirable. Such an example is found in the analysis of hemoglobin variants in single cells.\(^11\)

### 2.3 Electrochemical Detection

The potential of EC detection as an alternative method to UV absorbance detection to enhance sensitivity is indicated by the success of EC detection in HPLC. One EC detection method is based on a traditional method used for determining protein concentrations in biochemical analysis – the biuret reaction. In this method,\(^12\) the wall of the capillary is loaded with Cu\(^{2+}\)
ions by a rinse procedure and peptides migrating through the column form complexes with Cu$$^{2+}$$ ions released by the interaction. The complexes are then detected at carbon fiber microelectrodes yielding detection limits as low as 700 nM. Of interest is the fact that this method can be applied to the detection of cyclic peptides. Sensitive detection of this class of peptides is important because they often cannot be detected by FI methods since they lack a free amino group which is the functionality required for labeling by most fluorescent reagents. An alternative method for the detection of these molecules was demonstrated using a mixture of two cyclic pentapeptides obtained from solid-phase synthesis which were separated by CE with EC detection at a copper electrode.\(^{13}\)

Other EC detection methods reported include the analysis of bovine serum albumin using a carbon fiber microdisk array electrode\(^{14}\) and cytochrome c using a gold microdisk array electrode modified with cysteine.\(^{15}\) The potential of pulsed amperometric detection (PAD) at a high pH was demonstrated on a mixture of peptides released from recombinant coagulation factor VII by treatment with a glycopeptidase.\(^{16}\) By using integrated pulsed amperometric detection (IPAD) under mildly basic conditions (pH 9), mass detection limits in the picomole range were observed.\(^{17}\) EC methods based on the detection of thiols present in many peptides, such as glutathione, have been developed using modified electrodes\(^{18,19}\) or IPAD at various pH levels.\(^{20}\)

In general, to date, EC detection has not offered significant increases in sensitivity for peptide or protein analysis. However, this detection method relies on the EC behavior of the analyte rather than on its spectrophotometric activity monitored by UV or FI detection. This could have advantages in cases where species with high spectrophotometric activity are not separated from the peptideic analyte of interest during electrophoresis or when they are encountered in the background electrolyte. Necessarily, a peptide’s response to EC detection will depend on structural features different from those giving a spectrophotometric response, and thus the two methods can work in an orthogonal manner to give structural information. An example is given in Figure 2 in which comparison of PAD and 215 nm absorption detection methods indicate the presence of seven peaks which give significantly larger PAD responses relative to other peaks, owing to a higher content of specific oxidizable groups, such as oligosaccharide chains.\(^{21}\) Still, the development of more applications in peptide and protein analysis has been hampered by the lack of a commercial CE system available with an EC detector. Lack of commercial development is in turn probably tied to the recent developments in MS as a powerful and informative detection system.

### 2.4 Mass Spectrometric Detection

Among the various direct methods of detection for peptides and proteins, MS has the potential to become one of the most important of all, certainly the most important when qualitative information about the identity of sample components is desired. Thus it is that much effort has been expended in developing capillary electrophoresis/mass spectrometry (CE/MS) as a “user-friendly” technique since the first report of the coupling of the MS to CE in 1987.\(^{22}\) Since both CE and MS instrumentation have each been well developed independently, the key component is the interface. Advances in this area are to the point where commercial vendors have made CE/MS interface kits available for their instruments. For those CE instruments not designed for use with MS, there is an article which provides an experimental foundation on such interfacing with specific reference to application toward the separation of bioactive peptides and of a complex protein mixture.\(^{23}\) Before examining the various modes of interfacing and their suitability for peptide and protein analysis, it should be noted that the power of MS has been utilized extensively off-line on samples collected from CE. In this procedure, the matrix-assisted laser desorption/ionization (MALDI) technique\(^{24}\) of sample ionization has been utilized with great success for protein analysis. MALDI can provide good qualitative information on peptide identity but it is not a quantitative technique. Also, since it is technically not a detection technique but rather an off-line method, it will not be discussed further.

Although the potential of a variety of CE/MS ionization techniques has been explored, there appear to be two methods that have been used most often – fast atom bombardment (FAB) and electrospray ionization (ESI). An excellent chapter with references to these techniques and other interface methods has been published.\(^{25}\) Of these two methods, FAB is the more difficult to implement since it requires a high vacuum for ionization whereas ESI can produce ions at atmospheric pressure. Also, ESI offers the advantage of being able to produce molecular ions with greater than one positive charge. Mass spectrometers measure the intensities of species separated according to their mass-to-charge ratio, \(m/z\), and molecules such as large proteins, if only singly charged, would produce very high \(m/z\) ions, often beyond the range of the mass spectrometer. Multiple charges on the protein would bring the \(m/z\) values back down into the spectrometer’s range. Thus, a protein of \(M_r\) 25,000 possessing 25 positive charges can be detected on a spectrometer with a 1000 \(m/z\) range. In general, the ESI interface has found widespread use in current peptide and protein applications owing to its combination of versatility, as demonstrated above for producing multiply charged ions,
Figure 2 Comparison of CE analysis using PAD vs UV detection of a tryptic digest of recombinant tissue plasminogen activator.

facility in implementation, high mass accuracy (0.1%) and high sensitivity.\textsuperscript{(15,25)}

In ESI, a high electric field is generated between the tip of the capillary and the source of the mass spectrometer, causing charged liquid droplets to form. The droplets undergo a loss of solvent, resulting in an accumulation of charge until coulombic explosion occurs. This explosive process repeats to produce ultimately analyte ions in the gas phase. Of the different types of ESI interfaces that have been developed, all can be categorized as either sheath flow or sheathless designs. Figure 3(a) and (b) depict a sheath flow design typical of commercial interfaces and a new sheathless design, respectively. The sheath flow design utilizes the coaxial flow of a liquid to maintain the electrical contact necessary for the electrophoretic process. Also, the composition of the coaxial solution can be adjusted to permit the use of CE buffers that would otherwise perform inadequately when electrosprayed. The general performance in terms of the mass spectral considerations, such as spectral quality, are similar for all designs, whether sheathed or not. The major disadvantage of the sheath flow method is that it suffers from an inherent loss of sensitivity due to the mixing of the coaxial solution with the CE effluent. This loss is due not only to analyte dilution by the incoming solution but also to ionization of solutes present in the coaxial solution. Hence there exists an interest in developing sheathless designs similar to Figure 3(b) that possess the versatility and reliability of the sheathed design.\textsuperscript{(25)}

Although the use of sheath flow ESI results in a loss in sensitivity, the dilution of the CE buffer by the flow does offer some advantages in the terms of the variety of usable CE buffers. In order to be soluble, certain proteins may require relatively high salt concentrations and buffers up 0.1 M salt concentration are acceptable in ESI. Still, maximum sensitivity is obtained by using volatile buffers, such as acetic acid, formic acid or ammonium acetate, at low concentration. Unfortunately, surfactants such as sodium dodecyl sulfate (SDS) in the buffer generate intense background signals, thus limiting the use of MEKC as an electrophoretic separation mode.

The real power of CE/MS utilizing an ESI interface lies in its ability to give qualitative information about an analyte, but to what extent can that power be exploited for analysis of peptides and proteins? To answer this question, a number of different factors must be considered. These factors can be divided into (a) those characteristic of the analyte and its matrix, (b) those of the CE separation and (c) those of the MS performance in conjunction with the ESI interface.

Concerning analyte and matrix considerations, obviously any complexity in the matrix will diminish the usefulness to the extent that it interferes with the CE separation or the performance of the mass spectrometer. More importantly, the higher the molecular weight of the analyte, the more complex is the structure and, thus, the greater the range of masses that must be scanned in order to provide enough information to be useful in structural determinations. That is, a larger scan range would be required for an octapeptide than a tripeptide in order to determine its amino acid sequence.

The CE separation conditions will determine, in part, characteristics of the electropherogram such as resolution and, related to resolution, peak widths at half-heights ($w_{1/2}$). Of course, two well-resolved peaks will place less demand on mass spectral performance than would be otherwise, but also important is the $w_{1/2}$ of a particular peak. Depending on the analyte, this is generally in the range $1-5\text{s}$. Peaks with low $w_{1/2}$ put a demand on the performance of the mass spectrometer by requiring a high scan rate in order to sample the peak precisely.

Currently, quadrupole MS instruments are most often used in CE/MS systems using ESI as they give the best overall performance relative to expense. The main impediment they suffer is a lack of sufficient sensitivity due to the maximum number of ions actually introduced and detected per second ($\sim 6 \times 10^7$). It has been determined that if 10 scans are required to profile adequately a peak

\begin{figure}

\caption{Schematic illustration of CE/electrospray interfaces: (a) sheath flow (coaxial) and (b) exploratory sheathless design. (Reproduced from Smith et al.\textsuperscript{(25)} by permission of Academic Press, Inc.)}
\end{figure}
with a $w_{1/2}$ of 1–3 s (a scan speed of ~0.2 s) while scanning from $m/z$ 100 to 2000 in 0.2 $m/z$ steps, a dynamic range of only 5 would be achieved. If the scan speed is increased to 1.4 s while scanning only a range of $m/z$ 500 in 1 $m/z$ steps, the dynamic range increases to ~400.\(^{26}\) In general, as one lengthens the scan speed while lowering the scan range and the $m/z$ resolution, one gains in sensitivity and dynamic range. Thus, it has been stated that a scan range of a few hundred daltons at a scan speed of about 1 s is about all that can be expected with conventional instrumentation.\(^{27}\) The performance is limited in part to the fact that the CE buffer ions in addition to the analyte will be ionized in the process, thus reducing the percentage of total ions in the spectrometer due to the analyte. The use of a volatile buffers will decrease their contribution to the total ion current and improve performance.

Thus, in order to introduce the needed mass (in the range from high picomoles to low femtomoles) for MS analysis one generally needs relatively high analyte concentrations (in the micromolar range). A number of general methods have been developed for concentrating samples in CE regardless of the detection method. These procedures, which include sample stacking, transient isotachophoretic focusing and using packed precolumns, have been applied successfully to peptide analysis with MS detection.\(^{28,29}\)

Another simple way to increase capillary electrophoresis/electrospray ionization/mass spectrometry (CE/ESI/MS) performance is to use reduced elution speed detection (RES).\(^{30}\) In this method, as exemplified in Figure 4(a) and (b), the sample mixture is electrophoresed under the usual high field strength (300 V cm\(^{-1}\), in this case) until just before the first peak is ready to elute from the CE column. At that time, the field strength is dropped (to 30 V cm\(^{-1}\), in this case) to allow the separated component to elute more slowly from the column. This permits more efficient ionization of the solute in the electrospray source, resulting in a greater fraction of the analyte actually sampled. This can be utilized to do one or more of the following: (a) increase the scan speed and enhance sensitivity, (b) increase the scan range, (c) increase the $m/z$ resolution or (d) maintain the same scan speed and thus increase the number of scans for a particular peak. In the example cited, molecular weights were obtained with high precision and detection limits were lowered.

Since conventional CE/ESI/MS suffers from the restrictions listed above, it is often useful to use the system in an MS mode referred to as selective ion monitoring (SIM). This can be used when molecular weights and the $m/z$ values likely to be generated are known and one can select a particular $m/z$ value to monitor. The increase in sensitivity of SIM over the scanning mode is remarkable.

![Figure 4](image)

**Figure 4** Comparison of (a) constant field strength and (b) RES in the CE/ESI/MS analysis of a mixture of four proteins. Fields strengths: (a) constant at 300 V cm\(^{-1}\); (b) 300 V cm\(^{-1}\) until 1 min prior to elution of the first protein, when the field strength was reduced to 30 V cm\(^{-1}\). Reprinted by permission of John Wiley & Sons, Inc.)

For a test pentapeptide, the detection limits in the low femtomole range in the scanning mode are reduced to the low attomole range.\(^{25}\)

Alternative types of MS detectors are in various stages of development. One of the most promising techniques seems to be time-of-flight mass spectrometry (TOFMS), with its parallel detection and high repetition rates. A published report utilized a TOFMS system with a sheathless ESI interface to analyze test proteins, yielding low femtomole sensitivity and, more importantly, high mass resolution and accuracy (resolution greater than 6000 at 10 ppm).\(^{27}\) Interestingly, the amount of data generated by such detection systems is often beyond the storage and software capabilities of the computer systems used and only selected data acquired are actually recorded.\(^{31}\)

In terms of actual applications to peptide and protein analysis, CE/MS has been used primarily for the examination of standards\(^{32}\) and not “real-world” samples.\(^{28}\) A review indicated that 29 different peptides have been
analyzed by various researchers using CE/MS. While 27 of these were studied using a system with an ESI interface, only 12 used a FAB design. The same review also indicated that 21 kinds of proteins have also been examined by CE/MS. The majority of these were “developmental” studies not designed to answer biological or protein-synthesis problems. Examples of some of the exceptions include the use of CE/MS to determine protein purity. In one example, impurities in a preparation of a synthetic monoclonal antibody against herpes virus were detected. An example of a biological application can be found in the analysis of protein fragments in urine by on-line preconcentration followed by CE/MS.

One of the most promising areas of CE/MS application is that of peptide mapping and sequencing. Protein digests usually contain a large number of different peptide fragments as a result of proteolytic action. The high separating efficiency of CE affords good separation of the fragments while the power of MS lies in its ability to identify separated fragments. The electropherograms shown in Figure 5(a) and (b) are instructive in that both UV and MS detection were used in this analysis of a tryptic digest of tuna cytochrome c and, as expected, the general profiles of both electropherograms are similar. As discussed earlier, the relatively high-molecular-weight fragments were doubly charged and fell within the m/z range of the mass spectrometer, which can be used to identify peaks. Generally, most fragments detectable by UV absorption are observed by MS. Exceptions may be small entities such as amino acids and dipeptides owing to the difficulty in operating MS over a wide m/z range.

It should be noted that the equipment used to obtain the results in Figure 5(a) and (b) was a commercial CE system that had been modified to allow UV detection at half the MS detection time. Since the time of this publication, commercial equipment has become available that permits simultaneous UV/VIS and MS detection. Newer developments in the CE/MS analysis of protein digest have focused on aspects necessary in identifying components in small amounts of sample. One thrust of this effort is to develop CE capabilities to not only provide molecular weight values for the peptides in a CE peptide map, but also to sequence peptides by tandem mass spectrometry (MS/MS). A second aim is to be able to apply these techniques to the relatively low concentrations often encountered in analysis. A good example of the current research directed towards these ends is found in a report detailing the use of a solid-phase extraction (SPE) device coupled to a CE system which, in turn, was coupled to a triple quadrupole mass spectrometer and operated in the SIM mode. SPE led to picomolar detection limits while MS/MS analysis permitted the identification of peptides containing 9–20 amino acid residues. The procedure was applied successfully to the analysis of minute amounts of peptides that had been separated and isolated by slab gel electrophoresis. The enthusiasm and optimism of researchers in the field is evident in the following quotation: “It appears that continued development in the chemical and instrumental aspects of capillary electrophoresis/tandem mass spectrometry (CE/MS/MS) will push this technique to the forefront of the field of bioanalytical chemistry.”

Other research in the CE/MS area has focused on the development of alternative MS detection systems. Alternative detection systems can give superior performance but the systems are not readily available, may be difficult to interface, and are often expensive. Also
explored has been the application of MS detection to modes of CE other than conventional CZE. Since capillary isoelectric focusing (CITP) can accommodate much larger sample volumes than CZE and, in addition, analyte bands are concentrated during separation, improvement in concentration detection limits over CZE should be possible. CITP has been coupled to MS and applied to the analysis of proteins, but subsequent reports using the method have been sparse. MEKC coupled to MS would normally be prohibitive owing to interference of the surfactant, but one application used the method for the analysis of peptides by causing analytes to migrate through a micellar solution for separation and then into buffer containing no surfactant before entry into the mass spectrometer. Coupling CIEF to MS has also been accomplished and applied to separations of hemoglobin variants differing in pI by ~0.05 pH unit.

Overall, developments in MS detection systems have been proceeding at rapid pace and resources such as the biannual reviews on CE and MS that appear in June 15th issues of Analytical Chemistry are a helpful tool to help keep abreast of the field. One general trend that is evident is advancement of microscale MS detection methods. Various research groups are utilizing microfabricated devices for CE/MS with an ESI interface and evaluating the performance of such systems for biomolecule analysis. Microchip devices will be an important part of analytical instrumentation of the future and the high informational content available through MS detection would certainly make such systems extremely useful.

### 3 FLUORESCENCE DETECTION METHODS FOR DERIVATIZED SAMPLES

For the sensitive analysis of peptides and proteins using relatively affordable, commercially available equipment, derivatization of the analyte with a fluorophore and use of Fl detection, particularly laser-induced fluorescence (LIF), is the current method of choice. Sensitivity enhancements over UV absorbance detection are typically two to three orders of magnitude, with concentration detection limits usually in the low-nanomolar range. However, the method is not without its own problems.

Since Fl detection had seen widespread use in liquid chromatography (LC) prior to the advent of CE, a variety of derivatizing reagents for the introduction of the fluorophore have been developed for LC and are useful for CE analysis. Since the introduction of CE, new reagents have been introduced and often find applications in both LC and CE. Indeed, an extensive review of labeling reactions for small amounts of protein in CE and LC analysis has appeared, while another review has focused on derivatization in CE of all types of analytes, not just peptides and proteins.

Some of the more widely used derivatizing agents in CE are given in Table 1. No one reagent can be said to be the best for use in all situations, for a variety of reasons. An initial consideration would be the type of analyte. Large proteins contain multiple sites for a tagging reaction while a small peptide may contain few. From a cursory examination of Table 1, one can see that most reagents are designed to react with amino groups of the peptide or protein. If such a reagent is used with a large protein, multiple amino groups may be labeled, depending on the reaction conditions, while a small peptide may be singly labeled owing to the presence of only one available reaction site. The problem with having many potential labeling sites is that not all sites may react to the same extent, thus introducing greater heterogeneity into the analysis. Large variations in reactivity within proteins are a very real concern since each of the sites exists in a microenvironment with distinct reactivities such as the nucleophilicities of amino groups. Labeling of undesired sites, such as the cross-reactivity of thiols with amine

labeled reagents, is also a problem. One might consider adjusting the reaction conditions so that only one reactive site per protein or peptide molecule is labeled but, even if this could be achieved, the relatively small number of labels per molecule would result in low sensitivities, which defeats the purpose of labeling. Hence complete labeling of all desired functionalities is usually the goal of derivatization but can be difficult to achieve, especially for large proteins. In general, the reagents listed in Table 1 are more useful for small peptides than large proteins.

If heterogeneity results from labeling, then separation modes and conditions must be used to cause co-migration of a heterogeneously labeled analyte. An example of such a situation is found in a report in which four proteins of $M_r$ 20,000–77,000 were fluorescently labeled and then separated by SDS capillary gel electrophoresis. CE of labeled proteins exhibited the same separation efficiencies as for unlabeled analytes whereas the limits of detection were enhanced 20-fold over UV absorbance detection. In general, a derivatizing agent should not adversely affect the separation properties of the analytes, a requirement which is perhaps not too difficult to achieve for small peptides which are singly labeled but represents a challenge for large proteins.

Of course, it is also desirable to have a labeling reagent which reacts quickly in an efficient manner while producing a high yield of tagged analyte. These are general features one looks for in any reaction, but they can be particularly important in labeling reactions, especially when postcolumn derivatization is used. Most derivatization procedures are applied prior to injection in an off-line mode for convenience. This is often acceptable as long as one is careful to avoid excessive dilution of the sample with reagent, which diminishes the increase in sensitivity that one is striving for. Table 1 lists examples of a number of useful reagents. Precolumn derivatizations of peptides for CE analysis have been accomplished using some of the “classical reagents” such as fluorescamine, fluorescein isothiocyanate (FITC), 9-fluorenylmethyl chloroformate (FMOC) and o-phthalaldehyde (OPA). Unfortunately, some of these reagents do not exhibit an excitation maximum coherent with the wavelength of common, commercial lasers such as the He–Cd or Ar-ion lasers and thus exhibit diminished FI with such sources, resulting in decreased sensitivity. The development of specific reagents, such as 3-(4-carboxybenzoyl)-2-quinoline carbzoaldehyde (CBOCA), with an excitation maximum close to the 442 nm light of commercial He–Cd laser, has been realized and applied to the detection of peptides. Prior to the advent of CBOCA, naphthalene-2,3-dicarboxaldehyde (NDA) had been used to generate tagged peptides with a similar excitation maximum, and it has seen widespread use, including the analysis of single vesicles from a gastropod mollusk. Its popularity stems in part from the fact that the reagent is not inherently fluorescent but rather fluorogenic. Thus, unreacted reagent will not interfere in the FI detection of an analyte. Indeed, such interferences can make reagents such as FITC, which contains a fluorescent fluorescein group, unsuitable for protein analysis even though the labeled protein would have an excitation maximum near 448 nm, the output from commercial Ar-ion lasers. However, this laser’s light is close in wavelength to the excitation maximum of analytes tagged with 4-chloro-7-nitrobenzofuran (NBD-CI) and proteins so labeled have been used for molecular mass studies. Certain reagents have been developed to react with functionalities other than amino groups. These include benzoin, which labels arginine, and 4-methoxy-1,2-phenylenediamine which labels formylated tyrosine. An application of precolumn derivatization utilized tetramethylrhodamine-5-isothiocyanate (TRITC) to label an enkephalin in rat serum with detection limits in the low attomole range, suggesting that capillary electrophoresis/laser-induced fluorescence (CE/LIF) may be useful in the analysis of therapeutic peptides in physiological matrices.

While peptides can be fluorescently labeled by on-column derivatization, the method has seen little use since some of the reagents are present in the background electrolyte. Additionally, conditions must be optimized concurrently for derivatization of the analyte and the separation by CE. However, postcolumn online derivatization of peptides is an active area of research that offers some significant advantages over precolumn derivatization. There are fewer manipulations of the sample prior to injection, facilitating the ease with which the sample is analyzed. Also, a peak due to labeling reagent will not be present to hide analyte peaks. Most importantly, peptides are separated by their inherent electrophoretic mobilities unencumbered by the fluorescent tag and the anomalies this may produce, such as the previously discussed heterogeneity of multiply tagged proteins. Reaction kinetics must be fast, resulting in a restriction on the variety of useful reagents. The most popular reagents for this purpose are fluorescamine, OPA and NDA. Detection levels in the high nanomolar range were obtained in the analysis of neuropeptides and proteins using NDA, while another method used fluoresceamine to attain detection limits below nanomolar levels and the method was applied to the analysis of tryptic digests. An interesting application of this postcolumn derivatization method used NDA and mercaptoethanol to label the physiologically important peptide substance P (SP) and its metabolites. In this study, microdialysis samples were obtained periodically after perfusion of rat striatum with SP and subjected to...
CE/LIF analysis to generate the electropherograms in Figure 6.

A variation of postcolumn derivatization that enhances the specificity of the fluorescent tag is found in the use of an affinity-labeling technique. In this method, a fluorophore is bonded to a protein which will form an immune complex with the protein to be analyzed. One recent example of this system employs fluorescein-labeled fragment B of protein A to detect human IgG FC variants.\(^\text{56}\)

Overall, off-line precolumn derivatization is most commonly used but no reagent meets the ideal of selectively tagging an analyte at trace levels in an efficient, homogeneous manner. The matter is further exacerbated when analytes are found in complex matrices such as serum or urine. Although on-line precolumn tagging in CE has not been developed, on-line postcolumn methods seem promising, but the lack of commercially available systems has slowed application developments.

4 OTHER DETECTION METHODS

Peptides and proteins can be detected using other methods but reports using these techniques are rather isolated and have not been developed. These include the use of indirect detection in which a fluorescent species is added to the separation buffer and the analytes generate negative peaks as they displace the fluorophore. Although some increase in sensitivity over UV absorbance detection is gained in protein analysis using this method,\(^\text{57}\) it suffers from difficulties encountered in quantitation and also from the fact the method is non-selective. Another universal detection method applied to protein studies is thermo-optical absorbance (TOA) detection.\(^\text{58}\) In TOA, absorption of incident laser light by an analyte causes a temperature rise in the surrounding solution. A probe beam monitors this solution and changes in intensity proportional to analyte levels. This technique, though technically demanding, exhibits sensitivity similar to that of CE/LIF.
of LIF. Chemiluminescence has also been used for peptide detection in a peroxide–luminol-based system. As peptides bind to Cu²⁺ in the system, the ability of the copper to catalyze the reaction is diminished and less light is generated. This indirect method provides a rather limited method of analysis.  

The use of a biological system, such as a cell, as a detection method has also been introduced. Bradykinin peptides were separated by CE and the effluent containing the peptides was allowed to pass over the surface of cells containing receptors for the bradykinins. Binding to receptors caused release of Ca²⁺ which, in turn, caused an increase in the Fl of Fluo-3-AM, a calcium indicator.

5 COMPARISON OF DETECTION METHODS

In summary, there are a variety of CE detection modes for peptides and proteins and the suitability of any one method for a particular application depends on the conditions both of the sample itself and, when considering the cost of the method, the facility performing the analysis. For applications where sensitivity is not of paramount importance, that is, the analyte is found in concentrations in the micromolar range, UV absorbance detection is well suited to the task. It is robust, straightforward and relatively inexpensive. With minimal increase in expenses, a diode-array or multiwavelength version can yield useful information for identification purposes. It should be noted that preconcentration of a sample either off-line or on-line can effectively increase the ability to analyze lower concentrations to some extent.

EC detection is a method orthogonal to UV absorbance detection since it relies on the EC activity of the analyte. It has not been shown to be significantly more sensitive than UV detection but could offer a mode that may be less expensive than UV detection if commercialized. Miniaturization of this mode is being explored and EC detection may find its real future in microscale applications.

For CE analysis of peptides at nanomolar levels, derivatization with a fluorophore and LIF detection is usually recommended. The manipulations involved and the need for reaction efficiency can be concerns, but a variety of reagents exist which often suit the task. Use of this method on large proteins can be difficult, however, owing to problems arising from multiple, potential reaction sites.

Finally, MS detection may be the ideal detector in terms of the quality of information provided for peptide and protein analysis, particularly in the area of peptide mapping. However, the method is not a “mature” one. In the scanning mode, the sensitivity is lower than for LIF of derivatized samples and, at normal scanning rates, the scanning range is limited. Considering the relatively high expense of the system and the need for the user to interface the CE and MS units, perhaps with a commercial interface, one must consider carefully the value of such a detection method. Still, there is probably more method development occurring in this area of CE detection than in any other. Perhaps in the future, commercial CE/MS systems analogous to the ubiquitous gas chromatography/mass spectrometry (GC/MS) units may be found as part of the instrumentation in laboratories performing peptide and protein analysis.

The ability to resolve effectively peptides obtained by chemical or proteolytic cleavage is important in the structural investigation of proteins, whether it be minute amounts of protein isolated from a biological source or protein produced recombinantly for pharmaceutical use. Capillary electrophoresis (CE) can be used rapidly to resolve peptides electroforetically in free solution with a selectivity that differs from that of other separation approaches. In this article, we provide a description of the instrumentation for CE and the fundamental principles driving peptide separation at low and high pH.

Guidelines for method optimization of peptide injection and separation by CE are given along with a number of examples from the literature demonstrating the utility of CE for interrogating protein structure via CE-based peptide and glycopeptide analysis.

1 INTRODUCTION

Electrophoresis in capillaries (CE) has gained popularity as a separation technique applicable to both low molecular mass and macromolecular analytes. Separation in low ionic strength buffer is primarily due to differences in analyte charge-to-size ratio. The inability to separate neutral or uncharged analytes by capillary zone electrophoresis (CZE), where they migrate at the electroosmotic boundary, led to the development of micellar capillary electrophoresis (MCE) by Terabe et al. With this mode, an appropriate micelle-forming detergent is added to the separation medium, and separation of the analytes occurs as a result of both electrophoretic mobility (due to charge/mass) and chromatography (due to partitioning of the analyte into the micelles through hydrophobic interaction). Capillary isoelectric focusing (CIEF) involves filling a coated capillary to eliminate or severely reduce electroosmotic flow (EOF) with ampholines in an appropriate buffer, injecting the sample, focusing the analytes for a short time, and then mobilizing the focused analyte zones past the detector. This can be accomplished utilizing either a change in electrolyte media to effect EOF or by alteration of hydrostatic pressure; most commercial instruments allow the use of a combination of the two mobilization techniques. While capillary isotachophoresis (CITP) is a separate analytical mode of CE and one of the first to be explored in CE, it is currently used mostly as an on-capillary preconcentration technique. Finally, capillary gel electrophoresis (CGE) effects separation in either an immobilized polymerized matrix within the capillary (e.g. polyacrylamide) or in a free-flowing sieving matrix (e.g. methylcellulose). Sieving matrices are necessary with analytes, such as sodium dodecyl sulfate (SDS)–protein complexes or DNA, where the charge-to-mass ratio is identical regardless of size; here the separation is proportional to size. The primary modes used for the separation of peptides are CZE and MCE, although CIEF and CITP have their potential for specialized applications. CGE could be used for small SDS–peptide complexes with the appropriate matrix.

1.1 Instrumentation

A generalized configuration for CE instrumentation is given in Figure 1. With CZE, sample is introduced into
past a detector window where information is collected. Voltage, the analytes migrate through the capillary and voltage applied to the system. As a result of the applied solution that also contains the electrodes and a high voltage) or hydrodynamically (with pressure or vacuum).

Both ends of the capillary are then placed into buffer a buffer-filled capillary either electrokinetically (with low voltage) or hydrodynamically (with pressure or vacuum).

Both ends of the capillary are then placed into buffer solution that also contains the electrodes and a high voltage applied to the system. As a result of the applied voltage, the analytes migrate through the capillary and past a detector window where information is collected and stored by an appropriate data acquisition system. Two electrically driven phenomena contribute to the mobility of the analyte: electrophoretic mobility of the analyte and EOF of bulk solution. The charged analyte is mobilized electrophoretically in a manner that is a function of its charge and size, but is also carried by the net movement of buffer toward the cathode due to EOF. EOF is the result of the negative charge imparted to the inner surface of the capillary by the bare silica where cations form an organized double layer along the wall. Under an applied field, the double layer is propelled along the wall in the direction of the cathode. Unless altered through the addition of buffer additives, the use of a coated capillary or with low-pH buffers, the EOF is usually adequate to force the movement of all molecules toward the cathode and past the detector (Figure 2). This includes those with a net negative charge which are electrophoretically drawn toward the anode [assuming a polarity of (anode) → detector → (cathode)]. Subsequently, the analyte order in any given electropherogram has the fastest migrating species passing the detector window first and the slowest passing last (i.e. peaks from left to right represent the fastest to slowest migration). The capillary used for electrophoresis is made from fused silica and typically has an inner diameter in the range 20–200 µm (outer diameter of 200 or 375 µm) and an effective length of 7–100 cm. An external coating of polyimide makes a narrow-bore capillary surprisingly flexible.

1.2 Detection

There exist a number of on-line detection modes for CE, many of which have been developed based on high-performance liquid chromatography (HPLC) detection systems. These include ultraviolet/visible (UV/VIS) absorbance, fluorescence and conductivity. With some instrumentation, diode-array detection capabilities provide additional information. The absorbance spectra obtained through the use of scanning diode-array detection are often useful for component identification; however, sensitivity is somewhat compromised. Mass spectrometry (MS) shows promise as a versatile, powerful and sensitive detector for certain CE separations. There are defined limitations associated with the use of MS as a CE detector when interfaced via electrospray; however, low-pH separations in low ionic strength buffers are easily accomplished and very useful for peptide analysis.

1.3 Modes

Similar to the diversity associated with both conventional gel electrophoresis and HPLC, several modes of CE have been developed. The family of specialized techniques that
have resulted include CZE, MCE, CIEF and CGE. Of these, only CZE and MCE are pertinent to a discussion of CE of peptides. CZE, the most common CE technique, is utilized for both low molecular mass analytes and macromolecules. In contrast to conventional slab gels, separation using CZE is performed in free solution. This means that a gel matrix support is not required, although one can be implemented if desired. A necessity for CZE is that the analytes must be charged or chargeable as separation is achieved based on the species mass-to-charge ratio. CZE may be a misnomer because it implies that CZE is the only CE technique in which the solute forms a zone and migrates at constant velocity. However, CGE is also a zonal technique; thus, CZE is often referred to as free solution CE.

The inability to separate neutral or uncharged analytes with CZE led Terabe’s group\(^6\) to develop MCE.\(^7\) The use of an appropriate micelle-forming detergent in the separation buffer allows for separation to occur based on both electrophoretic mobility (due to charge) and partitioning of the solutes into the micelles. While this technique has mainly been exploited for the analysis of small, hydrophobic solutes, it has some applications in the analysis of peptides.

### 1.4 Introducing Peptides into the Capillary

As a result of the small dimensions of capillaries used in CE, the total capillary volume is typically in the microliter range. For example, a 47 cm x 50 µm capillary has a total capillary volume of 920 nl. Adhering to a commonly accepted “rule of thumb” restricting the injected sample volume to ~1% of the total capillary volume, sample volumes are limited to the nanoliter range to avoid overloading.\(^8\) The small sample volume injection into a capillary is usually accomplished by one of three methods. With hydrostatic injection, sample is introduced by pressurizing the inlet vial containing the sample or applying a vacuum to the outlet vial (opposite end) while immersing the capillary inlet into a vial containing the sample. Although much less common, sample introduction can also be accomplished through siphoning, which relies on gravity to introduce the sample into the capillary. Elevation of the inlet end of the capillary to a predetermined height while positioned in the sample vial allows for reasonably accurate delivery of the sample into the capillary and is used routinely with noncommercial (home-made) instruments.

With electrokinetic injection, the most popular method of sample introduction for peptides, the inlet is immersed in the sample and the outlet end placed in the separation buffer with a low voltage (1–10 kV) applied for a short period (usually several seconds) while the sample peptides migrate electrophoretically into the capillary. With peptides, one must be aware of the dependence of analyte injection on a number of parameters. One of the most important is the electrophoretic mobility of the sample components as they migrate into the capillary, in combination with the magnitude and direction of the EOF (the “bulk” flow through the capillary when current is applied). Other parameters which can effect this mode of loading include the sample buffer (particularly the ionic strength and pH) and the composition of the sample matrix. The strict dependence of this injection mode on electrophoretic mobility “biases” sample introduction; sample components with the highest electrophoretic mobility will be preferentially introduced over those with lower mobilities. Therefore, the results obtained with electrokinetic loading may not be a quantitative representation of the sample peptides. However, electrokinetic loading may be advantageous if the analyte of interest is only a small percentage of the total sample but has a much higher electrophoretic mobility than other constituents. Because of the unique charge characteristics of proteins and peptides (i.e. the presence of charged residues), the charge of the peptides of interest can be manipulated by conditions of pH to enhance their electrophoretic mobilities and provide a positive sample loading bias that may enhance detection by virtue of the selective injection of peptides and proteins preferentially over uncharged sample species. Another situation where electrokinetic introduction is advantageous involves electrophoretic separation in the presence of a polymerized or cross-linked matrix, where pressure injection cannot be used without physically damaging the separation matrix (e.g. SDS–protein complexes separated in a gel-filled capillary). It is noteworthy that sample matrices containing significant concentrations of electrolyte or salts are not efficiently electrokinetically introduced and must be either diluted or desalted before injection.

### 1.5 Electrophoresis-based Capillary Sample Concentration Techniques

One of the main drawbacks of ultraviolet (UV) detection in CE is the low sensitivity resulting from the inherently small dimensions of the flow cell (most commonly the inner diameter of the capillary) and the injected sample volume. As mentioned previously, introduction of sample volumes substantially larger than ~1% of the total capillary volume can result in poor resolution. While CE is a good mass detector, its poor performance as a concentration detector severely limits its use as an analytical technique to samples having nominally high concentrations (10 µg mL⁻¹ or greater). For this reason, the development of several approaches for “on-capillary sample concentration” have been pivotal to the acceptance of CE as a microanalytical technique. These
techniques are only briefly discussed here but may be investigated in greater detail from other sources.\(^{(9)}\)

1.5.1 Sample Stacking
One of the simplest methods for sample preconcentration is to induce sample “stacking” in a manner comparable to that developed by Hjerten for slab gels.\(^{(10)}\) This is easily accomplished in CE by exploiting ionic strength differences between the sample matrix and separation buffer.\(^{(11)}\) Sample components in an environment lower in ionic strength than the separation buffer experience an amplified field (and an enhanced electrophoretic mobility) and accelerate to the sample/separation buffer interface where they are slowed by the higher ionic strength of the separation buffer. Within a short time, the ionic strength gradient dissipates and the charged analyte molecules begin to move from the “stacked” sample zone toward the cathode. The subsequent reduction in the length of the sample zone as a result of “stacking” is roughly estimated to be the ratio of the ionic strength of separation buffer and sample matrix. Stacking can be utilized with either hydrostatic or electrokinetic injection and can typically yield a 10-fold enhancement in sample concentration and, hence, sensitivity (Figure 3). When possible, dissolving the sample in dilute separation buffer may be more advisable than in water since the dramatic differences in EOF between the sample plug and separation buffer may cause laminar flow within the capillary and, hence, lead to peak broadening.\(^{(13–16)}\) Since excessive heat produced in the sample plug may denature sample components,\(^{(17–19)}\) it may be advisable to “stack” at lower applied voltages or “ramp” to the separation voltage over several minutes.

1.5.2 Sample Focusing
An alternative approach identified for on-capillary stacking is sample “focusing” and is based on pH differences between the sample plug and separation buffer. This has been shown to be very useful for the analysis of peptides, mainly owing to their relative stability over a wide pH range.\(^{(8)}\) Focusing is accomplished by altering the pH of the sample to a point above the net sample pI (isoelectric point). The high-pH sample plug is flanked between low-pH separation buffer zones (i.e. an equivalent volume of low-pH separation buffer following introduction of the sample plug) and, upon applying a voltage, the negatively charged peptides in the initial sample zone migrate toward the anode. Upon entering the lower pH separation buffer, a pH-induced change in their charge state causes a reversal in the direction of mobility resulting in a “focusing” of the peptides at the interface of the sample (high pH) and low-pH buffer plugs. After the pH gradient has dissipated, the peptides, again positively charged in a low-pH separation buffer, migrate toward the cathode as a sharp zone. This approach, limited to samples that can withstand the inherent changes in pH without substantial denaturation, may yield as much as a fivefold enhancement in sample concentration and, hence, sensitivity. Other approaches, including isotachophoresis (ITP) sample enrichment,\(^{(20)}\) have been utilized successfully for peptide analysis and will not be discussed here.

**Figure 3** Field amplified stacking of peptides. Separation of a standard peptide mixture (peptide calibration kit, Bio-Rad, Richmond, CA, USA) in a phosphate buffer (pH 2.5) sample matrix at varying concentrations: bottom, 50 mM; middle, 5 mM; top, 100 mM. Separation conditions: 5 s hydrostatic injection; 10 kV running voltage; 50 μm × 27 cm (20 cm to detector) capillary. Peaks: 1 = bradykinin; 2 = angiotensin; 3 = α-melanin-stimulating hormone; 4 = thyrotropin-releasing hormone; 5 = luteinizing hormone-releasing hormone; 6 = leucine enkephalin; 50 μg mL\(^{-1}\) each. Separation buffer was 50 mM phosphate buffer (pH 2.5). (Reproduced by permission from Castognola et al.\(^{(12)}\))

2 THEORY OF ELECTROPHORESIS

2.1 Mobility of the Analyte
The electrophoretic mobility (μ) of a charged molecular species can be approximated from the Debye–Hückel–Henry theory (Equation 1):

\[
\mu = \frac{q}{6\pi\eta r}
\]  
(1)
where \( q \) is the charge on the particle, \( \eta \) is the viscosity of the medium and \( r \) is the Stokes radius of the particle. The mass of the particle may be related to the Stokes radius by \( M = (4/3)\pi r^3 V \), where \( V \) is the partial specific volume of the solute. While one might infer the direct proportionality of mass and radius of the particle, empirical data suggest modifications of Equation (1) to allow for the nonspherical shape, the counter-ion effects and nonideal behavior of proteins and biological molecules.\(^{[21]}\)

### 2.2 Resolution

The simplest way to characterize the separation of two components is to divide the difference in migration distance by the average peak width to obtain the resolution (\( \text{Res} \)) (Equation 2):

\[
\text{Res} = \frac{2(x_{i2} - x_{i1})}{w_1 + w_2}
\]

where \( x_i \) is the migration distance of analyte \( i \), the subscript 2 denotes the slower moving component and \( w \) is the width of the peak at the baseline.\(^{[22]}\) The position of a peak, \( x_i \), is determined by its electrophoretic mobility. The peak width, \( w \), is determined by diffusion and other dispersive phenomena (see below). For two neighboring peaks, \( w_1 \leq w_2 \), and (Equation 3):

\[
\text{Res} = \frac{x_{i2} - x_{i1}}{w_2}
\]

from the equation describing a Gaussian curve, the two peaks touch at the baseline when \( \Delta x_i = w_2 = 4\sigma \), and \( \text{Res} = 1 \), or (Equation 4):

\[
\text{Res} = \frac{\Delta x_i}{4\sigma}
\]

Substituting for distance \( (x_i = v_i t) \) and \( \sigma = (2D_i t)^{1/2} \) (the width of a Gaussian curve, the theoretical shape of the analyte plug) in Equation (4), we obtain Equation (5):

\[
\text{Res} = \frac{(\Delta \mu_{\text{app}} E) t}{4(2D_{i\text{avg}})^{1/2}}
\]

where \( \Delta \mu_{\text{app}} \) is the difference in apparent electrophoretic mobility of the two solutes and \( D_{i\text{avg}} \) is the average diffusion of the two solutes.

### 2.3 Efficiency

Probability theory allows us to assess the efficiency of the transport process.\(^{[23]}\) For a random walk process of length \( L \), made of \( n \) steps, the variance is given by Equation (6):

\[
\sigma = l(n)^{1/2}
\]

where \( l \) is the length of each step. If each step is independent of any other step, each contributes to the total variance of the process\(^{[24]}\) (Equation 7):

\[
\sigma_{\text{tot}}^2 = \sum \sigma_i^2
\]

Substituting from Equation (6) and rearranging, we obtain Equation (8):

\[
\frac{1}{n} = \frac{L^2}{\sigma_{\text{tot}}^2} = N
\]

The number of steps in the random process, \( n \), is inversely related to the number of theoretical plates, \( N \), a measure of the efficiency of the process.

We may substitute for \( L \) and \( \sigma \) in Equation (8) (as we did in Equation 5) to give Equation (9):

\[
N = \frac{(\mu_{\text{avg}} E)^2 t^2}{2D_i}
\]

where \( \mu_{\text{avg}} \) is the average mobility of the two solutes. Comparing the expression for \( \text{Res} \) (Equation 5) with that for \( N \) (Equation 9), we may combine the two to obtain an expression relating resolution to the number of theoretical plates (Equation 10):

\[
\text{Res} = \left( \frac{1}{4} \right) \left( \frac{\Delta \mu_{\text{app}}}{\mu_{\text{avg}}} \right)^2 N^{1/2}
\]

Equation (10) permits one to assess independently the two factors which affect resolution: selectivity, reflected in the difference of the mobility of the analyte(s); and efficiency, indicated by \( N \).

If \( \text{Res} = 1 \), then (Equation 11)

\[
N = \frac{16}{(\Delta \mu_{\text{app}}/\mu_{\text{avg}})^2}
\]

Another expression for \( N \) may be derived from Equation (8), using the width at half-height of a Gaussian peak (Equation 12):

\[
N = 5.54 \left( \frac{L}{w_{1/2}} \right)^2
\]

where 5.54 = 8 ln 2 and \( w_{1/2} \) is the peak width at half-height.\(^{[25]}\)

Note that it is misleading to discuss theoretical plates in electrophoresis. The concept comes from chromatographic theory, where a true partition equilibrium between a mobile solute and a stationary phase is the physical basis of separation. In electrophoresis, separation of the components of a mixture is determined by their relative mobilities in the applied electric field, which is a function of their charge, size and shape. The theoretical plate is merely a convenient concept to describe the analyte peak shape and to assess the factors which affect separation.
2.4 Sources of Variance

While $N$ is a useful concept to compare the efficiency of separation among columns, or between laboratories, it refers to the behavior of a single component during the separation process, and hence is unsuited for describing the separation of two components or the resolving power of a capillary. A more useful parameter is the height equivalent to a theoretical plate (HETP)\(^{(23)}\), (Equation 13):

$$\text{HETP} = \frac{L}{N} = \frac{\sigma^2_{\text{tot}}}{L}. \quad (13)$$

HETP might be thought of as the fraction of the capillary volume occupied by the analyte. It is more practical to measure HETP as an index of separation efficiency, rather than $N$, as the individual components which contribute to HETP may be individually evaluated and combined to determine an overall value. The variance of multiple dispersive phenomena on the analyte may be summed (Equation 14):

$$\sigma^2_{\text{tot}} = \sigma^2_{\text{diff}} + \sigma^2_{\gamma} + \sigma^2_{\text{int}} + \sigma^2_{\text{wall}} \quad (14)$$

Ideally, electrophoresis in a noninteracting medium should result in symmetrical zones of analytes. The length of time for separation would be determined by the differences in mobility of the two analytes and thus, in theory, given a long enough separation time, one should be able to resolve any two analytes. However, in the real world, materials do not behave ideally, and analytes frequently interact with the capillary or components of the separation medium. Therefore, we must consider the sources that create nonideal behavior.

A consideration of all the factors influencing $\sigma^2_{\text{tot}}$ includes not only diffusion, but also differences in mobility or diffusion caused by Joule heating (i.e. thermal gradients generated within the capillary during the electrophoretic process), the fact that the sample is not introduced as a plug of finite length, and interaction of analytes (which may not be the analyte of interest, but might affect electrophoretic mobility of the analyte of interest) with the capillary wall. While important in understanding separation in CE, this will not be discussed here and the reader is referred to literature which addresses this issue in detail.\(^{(13,26-30)}\)

3 APPLICATIONS

3.1 Predicted Separation: Simulated Versus Observed Migration

Two approaches have been used to evaluate the relationship between electrophoretic mobility and peptide charge and mass. The first modifies Equation (1) to Equation (15):

$$\mu = kqM^{-x} \quad (15)$$

where $x = 1/3$ assuming the spherical shape of Stokes law, $x = 1/2$ assuming the shape is related to the radius of gyration and proportional to the length of the peptide chain or $x = 2/3$ assuming the frictional forces are proportional to the surface area of the peptide.

Offord\(^{(31)}\) first proposed $x = 2/3$ based on studies of a large number of peptides by paper electrophoresis; this value has since been experimentally verified by numerous studies. Nyberg et al.\(^{(32)}\) found a good correlation with Offord’s model for a series of synthetic substance P (SP) peptides. Likewise, Deyl et al.\(^{(33,34)}\) found a linear relationship between the mobility of cyanogen bromide fragments of collagen between pH 6.9 and 10.5 and $M^{-2/3}$, surmising that the effect of molecular size was smaller than the effect of charge, at least for small- to medium-sized peptides.

A comparison of the three models was carried out by Rickard et al.\(^{(21)}\) using the mobilities of 33 peptides obtained at pH 2.35 and 8.15. The strongest correlation for peptides derived from the tryptic digestion of human growth hormone was with $x = 2/3$. In a study of 35 peptides with buffers at pH 2.0, 4.0, 7.0 and 10.0, Kurosu et al.\(^{(35)}\) found the best correlation with low-pH buffers and Offord’s parameter. Landers et al.\(^{(36)}\) obtained similar results for two peptides and their homo- and heterodimers using peptide migration time (proportional to $\mu^{-1}$), and Florance et al.\(^{(37)}\) arrived at a similar conclusion for motilin peptides at acidic, neutral or basic pH. Offord’s model has been substantiated by van de Goor et al.\(^{(38)}\) for modified adrenocorticotropic hormone peptides over a wide pH range and by Adamson and Reynolds\(^{(39)}\) with casein phosphopeptides.

A second, more empirical approach to define the relationship between electrophoretic mobility and peptide charge and mass was proposed by Grossman et al.\(^{(40)}\) Using the data from 40 peptides, ranging in length from 3 to 39 amino acids and in charge from 0.33 to 13, they fitted their mobility data to Equation (16):

$$\mu = k_1\ln(q + 1) + k_2 \quad (16)$$

where $k_1$ and $k_2$ were buffer constants and $n$ is the number of amino acid residues in the peptide. This modification of the basic equation includes contributions to size by shape and length of the peptide chain. A plot of mobility versus hydrophobicity suggested a causal relationship with increased molecular mass. However, because the size parameter is based on number of residues and not molecular mass of the amino acids,
these authors could not directly account for an increase in peptide molecular mass. A further difficulty lies in the inability to estimate the effects of buffer ions and ionic strength on the double layer of the peptide chain; however, one would expect an increase in the value of the exponent for a compact molecule as ionic strength increased. Issaq et al., comparing Grossman et al.'s model with Offord's, concluded that $kq/M^{2/3}$ gave the best correlation for small polyalanine peptides in 50 mM ionic strength buffer. However, Chen et al., carrying out a study similar to that of Rickard et al., found the best correlation with $M^{-1/2}$; likewise, Survay et al. obtained the best fit of their data to Grossman et al.'s model, rather than Offord's model. Castagnola et al. found a good correlation with Grossman et al.'s model with $n^{0.5}$ for trypic peptides from horse myoglobin.

Hilser et al. found that Grossman et al.'s model gave a better fit with trypic peptides derived from recombinant human insulin-like growth factor I than Offord's model. Further inspection indicated that both models inadequately treated peptide size, and a more complex treatment including thermodynamic functions of enthalpic and entropic contributions of polar and apolar moieties was required to improve the ability to predict peptide migration.

Compton attempted to reconcile the differences in these two approaches by developing a model based on Debye–Hückel–Henry theory, demonstrating that ionic strength would influence the mobility–mass relationship depending on the magnitude of the polymer molecular mass and the ionic strength of the buffer. In fact, mobility is a continuous and complex function of molecular mass between the limits of $M^{-1/3}$ and $M^{-2/3}$. For compact polymers in low ionic strength solutions one would expect mobility to reflect a dependence on $M^{-1/3}$; for larger molecules in high ionic strength buffers, $M^{-2/3}$ would dominate. Hence the dependence observed by Grossman and others would be indicative of moderate polymers in a medium ionic strength buffer.

In a comparison of the models of Offord, Grossman et al., and Compton, Cifuentes and Poppe found good agreement with any of the three models when constants were chosen appropriately. They attempted to account for the electrostatic interactions of the charges within the polymer, deriving Equation (17):

$$\mu = \frac{A[\log(1 + Bq)]}{M^C}$$  (17)

From a set of 48 peptides, these investigators obtained values of $A = 1758$, $B = 0.297$ and $C = 0.411$.

Application of Equation (15), (16) or (17) to the prediction of mobility of peptides is relatively straightforward. The charge on the peptide may be calculated by the Henderson–Hasselback equation at the buffer pH, using the ionization constants of the component amino acids. While the pKs of the side groups are typically assumed to be identical to those of the individual free amino acids, the C- and N-terminal ionization constants may differ by one or two orders of magnitude. Within the peptide, the ionization constants of individual residues may be affected by neighboring side chains, the local dielectric constant due to solvation and the ionic strength of the medium. Tabulated values for amino acid functions are available from Skoog and Wichmann, Rickard et al., Pennio and van de Goor. Several computer programs have also been developed to simplify the process by simply entering the sequence, if it is known (CHARGEPRO™ and PHYSCHEM™, IntelliGenetics, Mountain View, CA; Compudrug Chemistry, Budapest, Hungary). The predicted migration may then be adjusted (most typically by modifying the pH of the buffer) to obtain the desired separation of the analytes of interest.

With respect to buffer pH, a number of reports have evaluated the importance of the separation pH in predicting peptide mobility based on charge and size. Castognola et al. interrogated the importance of the Stokes radius as a function of the peptide pH. Since the Stokes radius of the peptide changes with pH, one would predict that the accuracy of peptide migration would change as solution pH is altered – this is not accounted for by the standard equation. Applying “best-fit” procedures to CE mobility data, the authors found the best predictive pH region to be 2.25–2.5 where the polymer Stokes radius relates to mass by the coefficient 0.68, close to Offord’s 2/3, and suggests that the Grossman et al. approach using the pKs of free amino acids is insufficient. This same topic was further explored by Castognola et al. using 2,2,2-trifluoroethanol (TFE) as an organic solvent in the separation buffer. This is a clever approach to interrogating predictive models since TFE modifies both the charge and Stokes radius. They found that predictions of mobility, size and charge were best in the pH range 2.0–2.5. This is likely due to the C-terminus being protonated, which the authors suggest eliminates an intramolecular ion pair causing a more compact form and exposing the apolar side chains; as a result the prediction becomes less accurate.

### 3.2 Interrogating Peptide Structure

As indicated above, selectivity (resolution or separation) in CE is determined by differences in analyte electrophoretic mobility. Electrophoretic mobility is a function of analyte charge and size (more specifically, hydrodynamic volume). The charge on the molecule is most readily influenced by the pH of the separation medium; hence the buffer and pH are typically the first operating parameters optimized. Additives, such as
organic solvents which modify microenvironmental pH and solvation of the analyte, or salts, organic or inorganic, which alter the ionic double layer and the protein microenvironment, can also be used. Compounds that complex or interact with specific functional groups may alter the size or shape of the peptide and thus affect mobility.

3.2.1 Buffer Type and pH

The choice of separation medium (buffer) is critical to obtaining successful separations of analytes. Once the optimum wavelength for detection of the analyte(s) has been established, a buffer is required that does not interfere with the ability to detect the analytes of interest but maintains the solubility of the analytes, maintains buffering capacity through the analysis and permits the desired separation. It is important to prepare buffers with reagents of the highest quality, including Milli-Q (or equivalent) purified water, and filtering the buffers through a 0.22- or 0.45-µm filter to remove any particulate matter. Buffers stored at 4 °C should be brought to room temperature and degassed before use.

A variety of electrolytes can be used to prepare buffers for CZE separations. With absorbance detection, a major requirement of all components of the buffer is a low UV absorbance at the wavelength used for detection. This restriction substantially limits the choices to a moderate number of nonUV-absorbing electrolytes. However, a number of UV-absorbing organic buffers have been used with success at low concentrations to minimize background absorbance. At low pH, phosphate, acetate, formate and citrate have been used effectively; in the basic pH range, Tris, tricine, borate and 3-(cyclohexylamine)-1-propane sulfonic acid (CAPS) are acceptable electrolytes. For detection modes other than UV absorbance, a number of other electrolytes can be utilized. In fact, for indirect detection, a buffer with high background absorbance to allow lower detection limits of analytes is desired; thus chromate or phthalate are often utilized. For electrochemical detection, the buffer must be compatible with the analytes and also present a stable background conductivity against which the analytes can be detected.

When information about the sample is available, it is advisable to choose a buffer pH that approximates the pK of the solute mixture. This choice is relatively simple with pure or partially purified preparations; however, with crude biological mixtures, the pKavg will typically be close to neutrality. Note that increasing the pH between 4 and 9 will result in an increase in the EOF. The buffer pH may be altered in a secondary manner by other parameters such as temperature, ion depletion of the buffer (caused by repetitive use of the same separation buffer) and organic additives. Examples of the effect of buffer pH on CE separation is given in Figure 4(a) and (b) for a series of peptides. The separation of a mixture of five peptide “isomers” representing residues 101–112 from the thyroid stimulating hormone (TSH) over a wide range of pH values is illustrated. At pH 2.5, all five peptides (differing only in sequence, not composition), which are identical in amino acid composition but vary in sequence, comigrate as a broad peak (not shown). At pH 8.61, the peptides migrate as two groups, while at pH 11.64 the resolution of four of the five peptides is observed.

3.2.2 Buffer Concentration and Ionic Strength Effects

Several parameters define the useful buffer concentration, including the capillary length and internal diameter, the applied electrical field strength and the efficiency of the capillary thermostating system. Generally, the use of moderately high ionic strength buffers is desirable for suppression of ion-exchange effects between the charged analyte ions and the ionic silanol groups on the capillary
wall. However, the current (Joule heat) associated with buffer concentrations greater than 100 mM may overcome the capillary thermostating capability of the system at higher applied voltages; excessive Joule heating may affect both resolution and analyte stability. Buffers that may be problematic include those containing high-mobility electrolytes such as chloride, citrate, phosphate, and sulfate. The excessive Joule heating associated with high-concentration buffers can be circumvented in two ways. The easiest solution is to lengthen the capillary so that a tolerable current is maintained (decrease the field strength). However, this will increase the effective capillary length and may compromise resolution or detection if excessive diffusion or analyte–wall interactions occur. A reduction in cross-sectional area of the capillary will also reduce heating by decreasing the current flux density, allowing for more effective dissipation of heat due to a greater surface-to-volume ratio. Alternatively, buffers that run at relatively low current (and Joule heat) can be used. One such buffer in the pH 7–9 range is borate buffer, which has been shown to be an excellent CE buffer at concentrations as high as 500 mM.\(^{55}\) This may be useful for the CE separation of fluorescently derivatized peptides in the neutral pH range. An added advantage of using a higher ionic strength separation buffer is the increased sample loading capacity that results from the on-capillary stacking effect, as described in an earlier section.

The method described by Nelson et al.\(^{19}\) termed the “Ohm’s law plot”, allows for facile determination of the ‘functional’ buffer concentration and the maximum voltage that can be utilized with the particular buffer system (i.e. the functional limit for capillary thermostating), and allowing for adequate equilibration, voltage is applied to a buffer-filled capillary (Figure 5) for short time intervals (e.g. 1 min) and the current recorded as the voltage is incrementally increased. When current is plotted as a function of voltage, loss of linearity indicates that the thermostating capacity of the system has been exceeded (i.e. the generated Joule heat is not effectively being dissipated). One should strive for heat generation of \(<1\text{ W m}^{-1}\) for optimum separation and it should not exceed a power of \(5\text{ W m}^{-1}.\(^{56}\)

Increasing the ionic strength of the separation buffer increases the thickness of the ionic double layer, and has the effect of decreasing the EOF, hence increasing the separation time. An advantage of increased ionic strength, in addition to the obvious improvement in buffer capacity, will be to decrease analyte–wall interactions.\(^{57}\) The net effect on the separation, therefore, will be to increase the resolution, provided that the capillary thermostating capability is not exceeded and that unwanted analyte dissociative processes (e.g. ligand–peptide/protein dissociation) do not occur. On the other hand, an increase in ionic strength might improve resolution in mixtures by decreasing non-specific analyte interactions. As mentioned above, increasing the ionic strength will also increase the current at a constant voltage, hence adequate thermostating of the capillary may become a concern. Also, use of buffers with poor transparency in the low-UV region (e.g. citrate, \(\lambda_{\text{max}} = 230\text{ nm}\)) may have adverse affects on detection sensitivity.

### 3.2.3 Augmenting the Separation Buffer with Additives

The selectivity in peptide separations can be enhanced with the use of buffer additives. Several classes of additives have been identified as applicable to CE and, as seen in Table 1, the additives are multifunctional, not only suppressing analyte–wall interactions, but also affecting analyte solubility and in some cases selectivity.

#### 3.2.3.1 Organic Salts

A number of organic modifiers have been used successfully in peptide CE with the effect being dependent on the nature of the additive. Positive effects on separation result from alteration of the solvation properties of the modified buffer on the analyte or diminished EOF due to changes in the thickness of the double-ionic layer (and hence the zeta potential) or reduction of the viscosity of the buffer. For example, the addition of 1,4-diaminobutane to the buffer has been proposed to enhance resolution by slowing the

![Figure 5 Determination of optimum separation parameters using the Ohm’s law plot. Current is plotted against applied voltage for each of three buffers as the applied field is incremented at 2.5 kV min\(^{-1}\). Buffers were: 100 mM phosphate (pH 2.5), made by dilution of phosphoric acid and titration with NaOH; 100 mM borate (pH 8.3), made by titrating 25 mM sodium tetraborate with 100 mM boric acid; and 100 mM CAPS (pH 11.0), made by titration of the appropriate concentration dissolved in water with NaOH. The lines indicate the linear portions of the plots. The departure from linearity indicates the excessive increase in current at the applied voltage, and is a reflection of the increase in the capillary temperature.](image-url)

EOF through a dynamic modification of the capillary wall. Ion-pairing agents, such as alkylsulfonic acid salts, have been used with success to resolve peptides.

Figure 6 demonstrates the influence of HSA on the separation of a series of peptides of identical amino acid composition but differing sequence. Here the resolution appears to be due to the differential solvation and/or the micro-environment of nearest neighbor effects on pK values of the charged amino acids.

3.2.3.2 Organic Solvents  Organic solvents, such as methanol or acetonitrile, decrease both the conductivity of the buffer and EOF through their ability to disrupt the ordered structure of the water molecules. Enhancement of resolution may result from a combination of the decreased EOF (i.e. increased on-capillary time), decreased thermal diffusion and improved analyte solubility. In Figure 6(a–c) the effect of acetonitrile concentration on the solvation and resolution of the same series of peptides is shown.

3.2.3.3 Chiral Agents  In the pharmaceutical industry, it is important to have the ability to resolve closely related impurities and degradation products in drug formulations. Skanchy et al. explored the separation of potential degradation products of a dipeptide using a novel anionic cyclodextrin, SBE[4]ₐₜ(1–10)ₚₜ-β-CD, as a pseudostationary phase for the CE separation. Evaluating a variety of neutral and anionic cyclodextrins as well as pH and the cyclodextrin concentration, they found that the stereoisomers of an Asp–Phe dipeptide (α-D,L, α-L,D, α-D,D) could be optimally resolved from the α-L,L parent compound using low concentrations of sulfobutyl ether-derivatized β-cyclodextrin at an acidic pH. This is significant in light of the fact that, to date, dipeptide stereoisomers have only been separated with chiral buffer additives or neutral cyclodextrins.

Figure 6: Enhanced peptide resolution afforded by the use of organic additives. The combined effect of acetonitrile and hexanesulfonic acid (HSA) on the separation of the peptides in 50 mM phosphoric acid (pH 2.0). Separation was carried out in a bare fused-silica capillary, 50µm ID × 57 cm long (50 cm to the detector) at 15 kV and 28 °C with detection at 200 nm. (Reproduced by permission from Oda et al.)

3.2.4 Other Modes 3.2.4.1 Micellar Capillary Electrophoresis of Nonglycosylated Peptides  MCE is a mode of CE which exploits...
the micelle-forming properties of surfactants to partion neutral molecules according to their hydrophobic character. While this mode has typically been used for the analysis of small, drug-like molecules, it has also been used with some success for the resolution of peptides. Grimm et al.\(^\text{63}\) improved upon a CZE method used for the separation of urinary imidodipeptides of prolidase-deficient patients exploiting MCE for disease screening. Using 65 mM SDS as the micellar phase in a pH 8.3 borate buffer, MCE separation allowed the collection and sequencing of almost all peaks for definition of the imidodipeptide composition of the urine. Once accomplished, imidodipeptide excretion patterns based on MCE separation may be used for disease diagnosis as well as determining severity. A follow-up paper from this group\(^\text{64}\) evaluated different surfactants in an attempt to optimize the separation of the urinary imidodipeptides. After trying three nonionic and four anionic detergents and also varying detergent concentration, pH and temperature, with and without organic solvents, they determined that the urinary imidodipeptides were optimally resolved in a pH 9.3 borate buffer containing 50 mM pentanesulfonate and 10% methanol at 10° C.

### 3.2.4.2 Capillary Isoelectric Focusing

Several researchers have begun to explore CIEF as a powerful alternative to CZE because it allows for large sample volumes to be loaded on the capillary without adverse effects on resolution. While more typically associated with protein analysis, recent studies have begun to show its utility for peptide analysis. Shimura et al.\(^\text{65}\) showed the effectiveness of peptide CIEF when coupled with laser-induced fluorescence (LIF) for sensitive detection. Using a nine-amino-acid peptide containing a cysteine, rhodamine labeling (at the thiol) was followed by trypsin digestion, which generated a six-amino-acid product. CIEF of the tryptic digest allowed the detection of the peptide product in the low picomolar range. Unfortunately, the authors did not demonstrate the application of CIEF with LIF to more complex samples. Taking a different approach, Wu et al.\(^\text{66}\) exploited imaged CIEF for the analysis of peptides as a means of circumventing the drawbacks associated with EOF or pressure mobilization of the focused zones in conventional CIEF. Whole-column imaging can reveal these methodological problems and their ramifications, including increased analysis time, uneven resolution and uneven mobilization speed. In this study, they demonstrated the successful imaged focusing of a synthetic peptide, although the significance of this sequence was not defined by the authors. The presence of 20% glycerol appears to be required for effective focusing and while both fluorocarbon- and polyacrylamide-coated capillaries were used in this study, it is not clear which was used in this particular experiment.

### 3.2.5 Peptide Dimerization

Landers et al.\(^\text{36}\) studied cysteine-mediated peptide homo- and heterodimer formation using CZE. Using a low-pH citrate buffer, they were able to monitor the kinetics of homodimer formation with a 28-amino-acid N-terminal cysteine peptide and a 13-amino-acid C-terminal cysteine peptide. Low-pH CZE allowed the deciphering of the time course for formation of the homo- and heterodimers when both peptides were incubated with \(\text{H}_2\text{O}_2\) with a 12-min separation. LeTourneau and Allen\(^\text{67}\) carried out similar studies using glycopeptides where homodimerization correlated directly with the antibacterial activity, e.g. vancomycin and ristocetin A. Using CZE in a neutral phosphate buffer, they were able to evaluate the dimerization of the three antibiotics (vancomycin, ristocetin A and LY264826) in the presence of a bacterial cell wall analog. Based on the mobilities, the glycopeptide antibiotic dimerization constants determined by CE were consistent in trend with those obtained by nuclear magnetic resonance (NMR) spectroscopy and sedimentation equilibrium, but generally smaller in magnitude.

### 3.2.6 Detection

#### 3.2.6.1 Derivatization

In order for CE to be effective for many of the applications involving peptide analysis in biological systems, sensitive detection schemes are needed. This often requires the employment of fluorescence detection and, in particular, LIF detection. Despite the intrinsic fluorescence of the aromatic amino acids (Tyr, Trp, Phe), fluorescent derivatization is often required for sensitive and unbiased detection. Common reagents for derivatization include fluorescein isothiocyanate (FITC), o-phthaldialdehyde (OPA), naphthalene-2,3-dicarboxaldehyde (NDA), fluorescamine and 3-(4-carboxybenzoyl)quinoline-2-carboxaldehyde (CBOCA), while less common derivatization reagents such as fluorescein succinimidyl ester (FSE) have also been tested.

Zhu and Kok\(^\text{68}\) studied the reaction kinetics for the postcolumn derivatization of peptides using fluorescamine and compared the labeling, both in effectiveness and detection sensitivity, with OPA. Using an uncoated capillary and a borate buffer at pH 9.5 for peptide separation, fluorescamine was found to be superior to OPA, providing limits of detection of ~0.1 µM. This was approximately 10 times better than the detection limits attainable with UV detection and, consequently, nanomolar to micromolar quantities of peptides are needed.

SP, a basic undecapeptide with a hydrophobic C-terminus, is a member of the tachykinin family, present in the central and peripheral nervous systems, and has a wide range of biological effects. The presence of this protein in brain fluid at picomolar concentrations has been
associated with schizophrenia and Huntington’s, Parkinson’s and Alzheimer’s diseases. In order to elucidate the function of SP and the contribution to its modulatory effects made by its metabolites, Whelpton et al.\textsuperscript{(69)} used CE in combination with HPLC to study the in vivo metabolism of SP in rat striatum. CE was used to separate the fractions from gradient elution HPLC and to avoid the high background signals when detecting at a low wavelength (214 nm) in HPLC. Based on the migration times, SP and significant amounts of its N-terminal fragments, SP (1–7) and SP (1–4), were detected but not the major C-terminal fragments at the concentration studied (10 nmol in the rat by intrastral injection). The CE results showed that the metabolism of SP has zero-order elimination kinetics with a rate of decay of 0.2 nmol min\(^{-1}\). The N-terminal metabolites may contribute to the overall pharmacological pattern of activity of the parent peptide as SP (1–4) and SP (1–7) are produced in vivo in the striatum in relatively large amounts. Kostel et al.\textsuperscript{(70)} also studied SP via direct sampling from brain tissue using microdialysis. Pseudo-real-time monitoring of tissue using this technique involves continuous sampling of brain fluid at approximately 1 µL min\(^{-1}\) and provides volumes compatible with CE. Using a postcolumn derivatization involving naphthalene-2,3-dicarboxaldehyde-β-mercaptopoethanol (NDA-β-ME) and an etched reactor in the membrane, they examined the detection enhancement in response to varying pH and reaction time. They observed a limit of detection of ~75–100 nM for lysine-containing peptides, but only 20–25 µM for non-lysine-containing peptides with 12-s reaction times.

Chen et al.\textsuperscript{(71)} studied the fluorescent labeling of [D-Pen\textsuperscript{5}]enkephalin (DPDPE), a synthetic opioid peptide used as a highly selective delta-receptor agonist in studies of receptor–ligand binding. Following solid-phase extraction (SPE) of serum samples on C\textsubscript{18} and fluorescent derivatization with tetramethylrhodamine-5-isothiocyanate isomer G, a CZE/LIF method was used to quantitate the DPDPE in rat serum. The on-column detection limit for this method was 1.3 amol (10\textsuperscript{-18} mol) of DPDPE, much higher than in HPLC (the analysis range is 50–100 µM) and CZE/UV detection (the detection limit is 0.4 µM). Their results show that this CZE/LIF method could be used for the sensitive and specific quantitation of therapeutic peptides in biological matrices.

3.2.6.2 Solid-phase Extraction/Capillary Electrophoresis for On-line Concentration and Analysis of Peptides

An alternative to derivatizing peptides for low-level detection using LIF is to concentrate the solutes of interest from large volumes on-capillary. This can be accomplished using solid-phase extraction/capillary electrophoresis (SPE/CE), which involves nothing more than creating a nanoliquid chromatographic column at the inlet of the capillary. Using as little as 100 µg of C\textsubscript{8} or C\textsubscript{18} resin packed into a microscale device as illustrated in Figure 7, a bed volume between 50 and 500 nL can be created. Guzman et al.\textsuperscript{(72,73)} led the way in this area, along with contributions from Debets et al.\textsuperscript{(74)} and Merion and co-workers.\textsuperscript{(75,76)} These devices, when fastened to the capillary inlet, can be used to adsorb solutes from 1 to 1000 µL with good efficiency and have been demonstrated to be effective for a variety of analytes.\textsuperscript{(77)} More importantly, SPE/CE has been shown to be extremely effective for peptide analysis at concentrations below the detection limit with standard CE by our group\textsuperscript{(78,79)} and others.\textsuperscript{(80)} Figure 8(a–c) shows the ability of the on-line SPE device for concentrating peptides. A mixture of standard peptides, when diluted below the limit of CE/UV detection (200 nm), can be detected when 20 µL of standard are concentrated on the SPE device and eluted in a ~50 nL volume. Figure 9(a) and (b) shows how this approach is effective for real peptide samples. Reversed-phase high-performance liquid chromatography (RPHPLC) fractions of 100 µL each are analyzed directly by CZE (once the acetonitrile has evaporated, leaving 55 µL). Interestingly, these fractions, containing peptides generated by an in-gel trypsinization of bovine serum albumin (BSA), including fraction 3, would all be expected to contain peptides based on absorbance with RPHPLC. However, two-dimensional analysis with CZE clearly shows peptides in all fractions except 3. This fraction was thought to contain a contaminant extracted from the acrylamide gel.
CAPILLARY ELECTROPHORESIS OF PEPTIDES

Figure 8  Comparison of standard CE and SPE/CE for the analysis of peptides. (a) Separation of a standard peptide mixture containing (1) bradykinin, (2) angiotensin, (3) α-melanin-stimulating hormone, (4) thyrotropin-releasing hormone, (5) luteinizing hormone-releasing hormone, (6) leucine enkephalin, (7) bombein, (8) methionine enkephalin and (9) oxytocin, all at individual concentrations of 50 mg mL⁻¹. Separation was carried out in a 57-cm capillary containing 50 mM phosphate buffer (pH 2.50) at 20 kV with the capillary thermostated at 25 °C. Sample was pressure injected for 10 s at 0.5 psi. Detection was at 200 nm. (b) Separation of the same mixture of peptides diluted 1:99 with 5 mM phosphate buffer (pH 2.50). Separation conditions as in (a). Sample was electrokinetic for 32 s at 8 kV. (c) Separation of the diluted peptide standards with SPE/CE where 20 mL of sample was loaded onto the packing by pressure (20 psi) for 1 min. Separation conditions as in (a). The bar represents 0.020 AU. (Reproduced by permission from Strausbach et al. 78)

Figure 9  Analysis of entire HPLC fractions in a single pass by CZE. (b) RPHPLC analysis of tryptic peptides from BSA. The peptides released from the tryptic digestion (0.4 µg) of 2 mg of BSA in a polyacrylamide gel slice were separated by HPLC and collected for two-dimensional SPE/CE analysis. The expanded figure identifies the peaks associated with the fractions collected from 31.5 to 34.0 min. (a) SPE/CE analysis of 55-µL HPLC fractions (100 µL prior to removal of acetonitrile) which were loaded onto the SPE capillary at 20 µL min⁻¹. Conditions for the separation were identical to those in Figure 8. (Reproduced by permission from Strausbach et al. 78)

4 POSTTRANSLATIONALLY-MODIFIED PEPTIDES

4.1 Glycopeptides

The biological role of oligosaccharides present in proteins has been subject to investigation since their discovery in the 1950s. These covalent components, originally thought to be artifacts, are now recognized to be important to the proper biological activities of these macromolecules, which include protein stability and solubility, biological recognition and function, antigenicity, transport and clearance. It has become increasingly clear that the intermolecular reactions associated with the function of glycoproteins involve both the carbohydrate and polypeptide portions of the molecule. 81 One aspect of glycoproteins that makes characterization difficult is their tendency to be “microheterogeneous”. Cells do not synthesize a single glycoprotein, but instead produce a family of glycosylation variants differing in their oligosaccharide content. It is thought that, while each member of this cellular pool of glycoforms may have
a unique biological activity, the molecular characteristics necessary for structural integrity are maintained. As a result, the combined functional activities of the glycoforms provide a continuum of biological activity which the cell can control with high fidelity by varying the relative amount of each glycoform.

From an analytical perspective, glycoproteins form a separate class of proteins whose structure is complicated by the presence of the surface carbohydrates. The oligosaccharides add a second dimension of complexity to the glycoprotein structure, as a result of the types of linkages possible between the oligosaccharide and the protein, as well as the variety of monosaccharides which compose the glycan. Oligosaccharides may be covalently bound to the protein via linkage to the amide nitrogen of the asparagine side chain (N-linked) or through the oxygen of serine, threonine and, occasionally, hydroxypoline (O-linked). In addition, oligosaccharides can be further classified based on the monosaccharides which constitute the glycan. The N-linked oligosaccharides are typically (1) “high-mannose”, composed of only mannose and N-acetylgalactosamine, (2) “complex”, containing a combination of galactose, fucose, neuraminic acid, mannose and glucosamine, or (3) “hybrid”, composed of the elements of both the high-mannose and complex oligosaccharides. O-Linked oligosaccharides generally have fewer branches than their N-linked counterparts, but have more diversity with respect to the monosaccharide units which constitute them. These include glucose, xylose, N-acetylgalactosamine and arabinose in addition to the monosaccharides found in the N-linked structures.

The chemical structure of oligosaccharides presents some unique analytical problems in comparison with other biologically active molecules, whether the intact glycoprotein (and its glycoforms) or the glycopeptides (formed from selective enzymatic digestion of the protein) are analyzed, or whether just the oligosaccharides are analyzed following cleavage from the protein. The molar absorptivities for carbohydrates are Remarkably low in the UV range and, therefore, preclude them from detection by fluorescence and absorbance methods, the most universal detection modes. Furthermore, saccharides are generally similar in structure, being polar and uncharged, and thus are difficult to separate in an unaltered form by RPHPLC or supercritical fluid chromatography (SFC). Oligosaccharides can be effectively resolved with a number of standard methods once appropriately derivatized: HPLC\(^\text{82–94}\) and gas chromatography\(^\text{95–99}\) using absorbance,\(^\text{100,101}\) refractive index,\(^\text{91}\) fluorescence\(^\text{102,103}\) and electrochemical detection schemes have been effectively used. The high resolving power of CE was recognized as a means to resolve individual glycoforms, providing the glycobiologist or carbohydrate chemist with the ability to answer many of the structural and biological questions that surround glycoprotein science. These studies made use of the extensive structural work done over the past several decades by glycobiologists. However, the difficulty in resolving the glycoforms of well-characterized glycoproteins has highlighted the idiosyncratic nature of some separations.

Taverna et al.\(^\text{158}\) analyzed the glycopeptides obtained by tryptic digestion of rt-PA and isolated two glycopeptide fractions by RPHPLC. CZE of glycoprotein fraction 2 (GP-2) in a bare silica capillary gave the same elution pattern whether the buffer was 150 mM borate (pH 9.1) or 100 mM phosphate (pH 6.6), suggesting that minimal borate complexation occurred due to terminal sialic acids. The glycopeptide fraction 3 (GP-3) was best resolved in a 50 mM tricine buffer (pH 8.5) containing 2.5 mM diaminobutane (DAB); the authors suggested that the improved resolution was due to the slowing of EOF by the divalent DAB.

Wu\(^\text{104}\) used CZE as a second dimension for the two-dimensional analysis of complex peptides resulting from the tryptic digest of recombinant tissue plasminogen activator. The first dimension, RPHPLC, lacked the resolution required to resolve the microheterogeneous glycopeptides, a task perfectly suited to CZE. Although high-performance anion-exchange chromatography (HPAEC) is capable of such separations, it suffers limitations in that only N-linked carbohydrates are separated and relatively large amounts of sample are required.

### 4.2 Micellar Capillary Electrophoresis of Glycopeptides

As mentioned earlier, MCE can be exploited for the separation of neutral molecules according to their hydrophobic character. This mode has also seen use for the resolution of glycopeptides, owing to the chromatographic partitioning of the neutral glycans into the micelle.

In the analysis of interferon-\(\gamma\) glycopeptides by CE, James et al.\(^\text{105}\) separated the glycoforms in a bare silica capillary using 400 mM borate–100 mM SDS (pH 8.5). The proteins separated into three groups: PG1, containing the diglycosylated forms (Asn 25 and Asn 97); PG2, containing the monoglycosylated protein (Asn 25); and PG3, the nonglycosylated protein. Borate buffers in the pH range 8.5–9 gave the best peak resolution and shape, although the glycoforms were not resolved without the addition of SDS. Further characterization of the protein by PNGase F digestion resulted in a loss of complexity in the PG1 region, with an increase in complexity of pattern in the PG2 area. Longer digestion led to loss of peaks in PG2 with increase in peaks at PG3, and a final collapse of PG3 into a single, broad band, suggesting denaturation or proteolytic degradation. Some lower molecular mass...
components were detected by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE), suggesting the presence of a contaminating protease in the PNGase F preparation. Neuraminidase altered the complexity within a PG group, reducing charge heterogeneity without changing the basic three groups, indicating maintenance of structural variants between the fractions.

Attempts to separate glycoforms of other glycoproteins again indicate the idiosyncratic nature of glycoprotein resolution. James and co-workers\(^{(104)}\) were able to separate the glycoforms of ribonuclease (RNAse) B and horseradish peroxidase, but were unable to resolve those of fetuin or \(\alpha_1\)-acid glycoprotein (AGP) in 400 mM borate–100 mM SDS (pH 8.5), suggesting that terminal sialic acid residues might prevent partitioning into the micelle, thereby precluding resolution with this additive.

Glycopeptides have been relatively easier to separate. Nashabeh and El Rassi\(^{(106)}\) investigated the CE separation of the glycopeptides obtained from AGP released by trypic digestion. A complex pattern of peaks was observed following electrophoresis in a polyethylene glycol (PEG)-coated capillary containing 100 mM phosphate (pH 5.0). Parts of the electropherogram were correlated with fractions obtained by chromatography of the digest on a concanavalin A–Sepharose column. The complex pattern was attributed to glycosyl heterogeneity without identification of structures.

The retardation of electrophoretic migration of peptides containing glycosyl groups is highlighted in an elegant study by Rush et al.,\(^{(107)}\) who produced a tryptic map of the glycopeptides of recombinant human erythropoietin. They were able to resolve 30 peaks in 80 min using 40 mM phosphate (pH 2.5), containing 100 mM heptanesulfonic acid as an ion-pairing agent (Figure 10). The electrophoretic pattern divided the peptides into nonglycosylated peptides migrating within 35 min and a glycosylated fraction from 40 to 80 min. Sialydase treatment resulted in peaks within the glyco window migrating faster, but still beyond 40 min, indicating that the neutral glycan retards the mobility of the glycan-containing peptides. N-Glycanase treatment resulted in a shift of peptides into the glycone window (<40 min), as would be expected. Combining high-performance CE and HPLC as two-dimensional techniques, the individual glycosylation sites, Asn 83, Asn 24 and Asn 38, and an O-linked site were mapped. The authors suggested a strategy for the identification of glycosylation sites by a combination of RPHPLC and CE and possible assignment of structural identity of glycoforms based on the alterations in migration resulting from glycosidase digestion. This is certainly feasible based on the development of instrumentation for rapid two-dimensional HPLC/CE analysis by Larmann et al.\(^{(108)}\) Sampling directly from a one-dimensional RPHPLC separation at regular intervals with CE analysis completed on the low seconds timescale in the second dimension, analysis of fluorescently labeled peptides from a tryptic digestion of horse heart cytochrome \(c\) was possible. Clearly, this type of analysis would be extremely useful for glycoprotein characterization.

Rudd et al.\(^{(109)}\) isolated five peaks, corresponding to the individual manno-5- through manno-9-containing glycoforms, from RNAse B. Analysis of oligosaccharides obtained by hydrazinolysis gave a pattern of five peaks, corresponding to the manno-5-through manno-9-glycomers. Using isolated fractions of RNAse B, Rudd et al.\(^{(110)}\) investigated the structure–function relation of the glycosylation. Enzymatic digestion by \(\alpha\)\(_{-}\)satoi \(\alpha\)-mannosidase reduced manno-5 to -9 (RNAse B5-9) glycomers to manno-5 (RNAse B5). RNAse B manno-1 (RNAse B1) was obtained by digestion with jack bean \(\alpha\)-mannosidase. Mannosidase from \textit{Helix pomatia} was used to produce a manno-0 (RNAse B0) isoform containing just the core \(N\)-acetylglucosamine residues. All glycoforms were separated on 50 \(\mu\)m x 100 cm bare silica capillary in 20 mM phosphate–50 mM SDS–5 mM borate buffer (pH 7.2) using a discontinuous voltage ramp, and collected preparatively. The isolated protein fractions showed no gross alterations in structure as reflected by H/D exchange rates monitored by NMR spectroscopy. Pronase proteolysis suggested no gross structural changes, as all glycoforms were more resistant to proteolytic digestion with a \(t_{1/2}\) of 450 min for the glycosylated RNAses compared with 300 min for RNAse A. Comparing RNAse activity on whole-cell RNA, the glycoforms were more active: RNAse A (1.0, relative activity): RNAse B0 (1.6) = RNAse B1.

**Figure 10** CE separation of peptides and glycopeptides from recombinant human erythropoietin. The group of peaks with the faster mobility represent nonglycosylated peptides, and those with retarded migration are glycosylated. Experimental conditions: 40 mM sodium phosphate buffer with 100 mM heptanesulfonic acid at pH 2.5; 16 kV running voltage, 110 \(\mu\)A; 50 \(\mu\)m x 75 cm (50 cm to the detector). (Reproduced by permission from Rush et al.\(^{(107)}\))
(2.2): RNase B5 (3.6) = RNase B5–9 (3.8). These studies support the hypothesis that there might be a range of functional activity in the cell provided by glycoforms of an enzyme. Rudd et al. (116) noted that the individual glycomers might have differential activity against purified fractions of RNA; this hypothesis was not tested.

5 CONCLUDING REMARKS

As the Proteome Project enters our scope as the latest challenge for researchers in a quest to understand cellular processes in normal and pathological states, the ability to perform rapid and information-rich analysis of peptides will become critical. CE is a key part of the analytical arsenal that will be used to interrogate the complex array of components constituting the proteome. While CE has been established as a bona fide technique for peptide analysis, it is clear that we have not yet fully exploited this technology for application in the vast arena defined as peptide and protein analysis. The potential clearly exists for CE to provide a rapid means for not only interrogating peptide primary structure, but also for characterizing the myriad of post-translation modifications (e.g. phosphorylation, ribosylation, myristolation, methylation and hydroxylation). These capabilities will surely be enhanced by the effective interfacing of CE with other techniques. For example, Severs and Smith (112) have already demonstrated the power of MS as a detection method for CE in peptide analysis, and Moore et al. (111) have demonstrated, convincingly, the power of CE as part of a two-dimensional analysis of peptide mixtures. As these and other technological advances mature, as method development and instrumentation improve and as approaches for sensitive detection both in hardware and chemistry improve, CE-based peptide analysis will evolve into a robust, turnkey operation applied to a diverse array of applications.

1 Introduction

1.1 Electrophoresis in a Capillary

Electrophoresis is a process that involves the movement of charged particles in an applied electric field. This concept, first defined by the moving boundary electrophoresis experiments of Tiselius in 1937, was eventually adapted to slab gels in the early 1960s. In this format, electrophoretic separation is performed through a cross-linked, porous gel polymerized between two plates. Slab gel electrophoresis, as well as adaptations in the tube format, provided the basis for a variety of electrophoretic modes to evolve and has been and remains a dominant force in the field of separations. In the early 1980s, Jorgenson and Lukacs revitalized a technique that Hjertén had pioneered more than a decade earlier and, thus, introduced CE to the scientific community.

1.2 Instrumentation

CE involves the separation of analytes in narrow-bore capillary tubes which are typically composed of fused silica. The attractive aspects of CE stem from the fact that the instrumental control common to chromatography is now possible with electrophoresis. CE circumvents the labor-intensive and time-consuming processes associated with conventional electrophoresis (casting, loading, running, staining, and destaining) with little or no sample preparation, decreased analysis time, and on-column detection. Capillaries are typically less than 100 µm inner diameter by 375 µm outer diameter by 20–100 cm in length and provide a high surface-to-volume ratio permitting rapid dissipation of Joule heat. As a result of the microscale dimensions, applied electric fields as much as 50 times that associated with slab gels can be routinely employed, enabling separations on the order of minutes or even seconds. A direct consequence of the microscalar nature of the capillary dimensions is the minute quantities of buffer and sample required for analysis. The total volume of the capillary, routinely 0.4–5.0 µL, translates to only microliters of reagent consumed per run. More importantly, the sample volume injected is restricted to approximately 1% of the total capillary volume (as low as 0.2 nL) requiring as little as 2–5 µL of sample for repetitive separations. The use of small volumes allows for the capillary to be easily rinsed and regenerated between method development that are important for achieving optimal separation. Finally, each separation mode, including capillary zone electrophoresis (CZE), capillary gel electrophoresis (CGE), and capillary isoelectric focusing (CIEF), is discussed with particular attention to its niche in the realm of protein and glycoprotein analysis.

1.3 Modes of Capillary Electrophoresis

As a result of their complex nature, the separation of proteins and glycoproteins by capillary electrophoresis (CE) is a challenge. Fortunately, a number of approaches allow for effective analysis of these biomolecules. Of particular concern is the proclivity of proteins and their glycoconjugates to adsorb to the capillary wall. Various covalent and dynamic capillary coatings are described which minimize this effect. We also address general concerns including electrode polarity, capillary conditioning and
analyses with moderate pressure (10–50 psi), vacuum, or even gravity. The dramatic decrease in the amount of reagents used in CE, compared with slab gel methods, is directly linked to another advantage with the capillary-based electroosmotic approach – cost. Although the capital investment for commercial CE instrumentation or a homemade system is initially more expensive than slab gel equipment, the reduced cost for reagents, and small sample volumes, combined with dispensing of staining procedural costs, and the added benefit of automation, make CE an economical alternative.\(^7\)

In addition to providing an instrumental approach to electroosmotic protein separations, CE allows for an on-line detection system, eliminating the need for staining and destaining procedures characteristic of the slab gel format. An electroosmosis technology that allows for evolution of detection from the semiquantitative staining procedure to direct wavelength-specific on-line detection has obvious merit. The problems associated with gel-based staining methods for detection of proteins are well-established and dependent heavily on a variety of parameters (stain source, stain age, temperature, specific protein, etc.), all of which affect staining efficiency and, thus, quantitation. Staining procedures are particularly problematic with glycoproteins as a result of stain binding interference by surface carbohydrate.

Although both optical and electrochemical detection methods have been demonstrated with CE, the optical techniques have been implemented more universally than the others. Ultraviolet/visible (UV/VIS) detection is the simplest to employ and applicable to a wide range of compounds including many biopolymers. However, the short pathlength of the optical cell (which is the internal diameter capillary itself) leads to poor concentration sensitivity and detection limits in the \(10^{-6}–10^{-8}\ \text{M}\) range. It is in this respect that fluorescence detection is important, providing a more selective detection scheme and, in comparison with UV/VIS detection, sensitivity that is 100–1000-fold greater. Unfortunately, only the amino acids tryptophan, tyrosine, and phenylalanine fluoresce naturally and, therefore, most proteins must be tagged prior to analysis for laser-induced fluorescence (LIF) detection using simple (e.g. argon ion lasers) systems.

Yet another problem encountered with gel-based separations is poor reproducibility, particularly with two-dimensional systems. The quantitative reproducibility of CE is very good with typical migration time relative standard deviation (%RSD) values between 0.1% and 1.0%. In addition, for well-characterized CE systems, protein separation efficiencies reach \(10^4–10^5\) theoretical plates.\(^8\) Thus, a technique surpassing the performance of its gel counterpart emerges, providing rapid, high efficiency, and reproducible separations with the added value of on-line detection and automation.

\[1.2\] Instrumentation

A diagram of the instrumental set-up for CE is presented in Figure 1. The necessary components for this system include a capillary (outer surface polyimide-coated), a high voltage supply, two buffer reservoirs capable of accommodating the capillary and platinum electrodes, and an on-line detector. To perform a separation, the preconditioned capillary is filled with buffer and then sample is introduced at the inlet by pressure, vacuum, gravity or an applied potential. Using an uncoated (internal) fused silica capillary, under normal polarity, the inlet will be positive (anode) and the outlet negative (cathode). Both ends of the capillary are transferred to their respective buffer reservoirs where a separation voltage (up to 30,000 V) is applied. The charged species present in the sample plug migrate with an electrophoretic mobility deemed by their charge and mass (under nondenaturing conditions), and pass through the on-line detector, where information is collected and stored electronically.

Conventional separation techniques (such as gas chromatography (GC) and high-performance liquid chromatography (HPLC)) employ pressure gradients to pump the mobile phase and solutes from the column inlet to the detector. CE is unique in this respect in that it does not utilize a mechanical pumping mechanism for bulk flow. Instead, the physical configuration and chemical make-up of the capillary allow for an electric field-driven pumping of bulk solution during the electrophoretic process. Using an uncoated fused silica capillary and a normal polarity configuration (inlet \(\rightarrow\) anode, outlet \(\rightarrow\) cathode), ionized silanol groups on the capillary wall induce the formation of a double layer of cations (and their hydration spheres) which produce an electroosmotic flow (EOF) in the presence of an applied field (Figure 2a). The magnitude of this flow becomes significant (\(\approx 10^{-4}\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}\)) above pH 5–6 where the silanol groups will be largely deprotonated. EOF is responsible for the flow of analytes, regardless

\[\text{Figure 1}\] Diagram of a CE instrument. An enlarged section of the capillary is shown to highlight the dimensions.
Figure 2 EOF and effects of wall coatings. (a) In most pH ranges (pH 3–11) a bare fused silica capillary has a negative surface charge. Consequently, cations in solution align, forming a positively charged double layer. Under an applied field and normal polarity (inlet → anode, outlet → cathode), the positive ions will move toward the cathode resulting in bulk flow toward the detector. (b) Coating with a nonionic layer shields the surface charge contributed by the silanols and thereby reduces the EOF. As the pumping mechanism has been minimized, the electrode polarity must be chosen so that molecules of interest migrate toward the detector. (c) Capillary coatings changing the effective charge of the wall from negative to positive will result in the formation of an anionic double layer. Consequently, the EOF is reversed and will be in the direction of the inlet (anode). Thus, only species with an electrophoretic mobility greater than the EOF will reach the detector under normal polarity. Reverse polarity may be employed for the detection of analytes with low electrophoretic mobility.

of charge or size, to the detector. Thus, even neutral and negatively charged species will pass the detector as a result of the EOF, in most cases, being greater than the electrophoretic mobility of the anodically mobile species. EOF is largely (but not solely) governed by the buffer pH; a low-pH buffer produces relatively low EOF as a result of the decreased number of deprotonated silanols. Figure 3 illustrates the pH dependence of EOF. It is important to note that EOF results in the bulk movement of all analytes past the detector, therefore, a decrease in EOF will result in a situation where only solutes of like charge can be separated.$^9$

1.3 Modes of Capillary Electrophoresis

Similar to the diversity found with standard gel electrophoretic techniques, several modes of CE have been established. These include CZE, micellar electrokinetic chromatography (MEKC), CIEF, and CGE. Although capillary isotachophoresis (CITP) has already been developed as a stand-alone mode for the analysis of proteins, it is primarily used as a preconcentration technique in CE. A basic knowledge of the existing similarities and defining differences between the modes is often necessary for optimizing a given separation. For instance, this may involve nothing more than use of a buffer additive to switch from one mode to another. Of the four main modes (CZE, MEKC, CGE, CIEF) only CZE, CGE, and CIEF play a major role in the CE analysis of proteins. These are described in the sections where they are discussed.

2 CAPILLARY ELECTROPHORESIS ANALYSIS OF PROTEINS AND GLYCOPROTEINS

Proteins and glycoproteins present a unique challenge to the separation scientist as a result of their complex nature. Crude or partially purified protein preparations are not trivial to analyze by CE due to the diverse nature of molecular masses and pH- and temperature-dependent stabilities that may be represented in the mixture. With
traditional denaturing slab gel electrophoresis, these inherent variations do not present a problem but, within the realm of CE where non-denaturing analysis is easily executed, these become important parameters.

Additional considerations associated with CE stem from the fact that separation is carried out in a capillary composed of fused silica, a substance with poor biocompatibility, especially for proteins. Under non-denaturing conditions, proteins have a propensity for adsorption to the capillary wall. This interaction must be minimized or negated if CE separation of proteins based on both charge and size is to be successful. A number of approaches are addressed in this review to deal with problematic areas of protein analysis. Once solved, CE evolves into an extremely powerful technique for biomolecule analysis.

Finally, glycoproteins are a group of macromolecules with complexity beyond that of nonglycosylated proteins as a result of the carbohydrate structures present on the protein surface. The carbohydrate moieties on the protein have been shown to be associated with numerous biological functions, including solubility, antigenicity, protein folding, transport, and clearance from the cell. Additionally, abnormalities in glycosylation have been found to lead to or be the result of a number of pathological states. To further complicate the issue, even purified preparations of certain glycoproteins are not trivial to analyze electrophoretically as a result of the carbohydrate content of the protein in biological systems. These glycoforms arise from the cellular production of a set of proteins that are identical in their polypeptide structure, but differ in their glycosylation with each serving a specific function within the cell. This microheterogeneity is thought to play a critical role in the high fidelity control function within the cell. This microheterogeneity is often difficult if not impossible to accomplish with conventional electrophoretic formats. However, as will become clear in the sections that follow, non-denaturing separations by CE provide a new tool for interrogating glycoprotein structure and microheterogeneity.

3 FACTORS AFFECTING SEPARATION

3.1 Capillary Wall Interactions

One of the major problems that had to be addressed with early attempts to resolve proteins under non-denaturing conditions in fused silica capillaries was their nonspecific adsorption to the capillary wall. In the earliest studies by Jorgenson and Lukacs, the equation governing separation efficiency (derived by Giddings for chromatography) was simplified based on the fact that, as this was electrophoresis and not chromatography, the partition coefficient $k'$ in the radial diffusion term was essentially zero, giving Equation (1), where $D$ is the diffusional coefficient

$$N = \frac{\mu V}{2D_{n,T}}$$

This made CE, in a sense, “antichromatography”; with the assumption that $k' = 0$, band broadening (number of theoretical plates) would be primarily dependent on axial diffusion contributions. Due to the large molecular mass of proteins, diffusion would be relatively small and, therefore, calculated efficiencies of the order of $10^6$ theoretical plates would be expected. However, this was not observed, even under the most ideal separation conditions. The inability to achieve predicted efficiencies was attributed to adsorption of analytes onto the highly negatively charged silanol surface of the capillary wall, indicating that $k' \neq 0$ and, therefore, cannot be ignored. Swedberg’s group at Hewlett-Packard has provided insight into this and shown that even small $k'$ values (as low as 0.001) result in a substantial decrease in the achieved theoretical plate number. Accordingly, attention must be paid to define CE conditions that strive to meet the assumption that $k' = 0$ (i.e. no wall interactions) for both peptides and proteins.

This can be accomplished for CE-based peptide separations with relative ease by working at pH extremes. At a basic pH of 10–11, both the capillary silanol groups and the peptides are fully deprotonated and, hence, negatively charged allowing for repulsion to prevent adsorption. At acidic pH of 1.9–2.5, the capillary silanol groups are fully protonated and, therefore, neutral in charge, while the peptides are cationic with no predominant proclivity for adsorption to the wall. Consequently, acidic peptides, difficult to resolve by reversed-phase HPLC methods, are readily analyzed in simple, low-pH buffer systems, such as 100 mM sodium phosphate, pH 2.5. This approach is extremely effective for peptide separations due, in part, to the fact that the peptides can easily withstand the extreme nature of the separation conditions. This is not the case with proteins where their stability is questionable outside the physiological pH range (pH 7.5). Although there have been some examples demonstrating that working at extremes of pH can be effective for protein analysis, this is more the exception than the rule and precludes analysis in the most relevant pH range (physiological). Furthermore, adsorption is still frequently observed even at high pH values (e.g. pH 10.0) above the isoelectric
point (pI) of many proteins. One must be cognizant that the pI is a net charge for the molecule and does not account for localized surface basic amino acids which may retain a positive charge even at extreme pH ranges. This phenomenon is exacerbated with proteins due to their increased surface area.

Thus, a challenge inherent in performing protein separations in silica capillaries, which is not encountered in HPLC or conventional electrophoresis, involves determining conditions that will minimize or even eliminate protein–wall interaction (i.e. \( k' = 0 \)). Approaches for doing so have been evaluated extensively and involve either covalent or dynamic modification of the capillary wall or augmentation of the separation buffer composition. These are addressed in the sections that follow.

### 3.2 Buffer

Buffers play a major role in achieving a successful separation in CE. Ideally, CE buffers must maintain the solubility of the analyte, have good buffering capacity in the pH range of interest, and have low absorbance at the detection wavelength desired (typically 200 or 214 nm for proteins). There are a number of considerations for selecting an appropriate separation buffer. Most important is choosing an electrolyte. A number of effective electrolytes have been identified for protein separations at slightly acidic and basic pH ranges with borate and phosphate often employed. Another consideration is the ionic strength of the buffer. Higher buffer concentrations are obviously beneficial for increasing the buffering capacity of the solution, but they also influence the EOF by directly affecting the thickness of the ionic double layer (increased ionic strength \( \rightarrow \) decreased EOF), and are associated with more current at high applied fields. As detailed in the article in this encyclopedia on Capillary Electrophoresis of Peptides, an Ohm’s law plot (OLP) can aid in defining the functional concentration for a particular separation buffer.[18]

### 3.3 Capillary Coatings

In 1986, Lauer and McManigill[19] published a seminal paper demonstrating that protein separations could be achieved successfully in a bare silica capillary if wall adsorption was addressed. Over the past decade, research into the development of novel technologies for masking or eliminating the negative charge of the capillary wall has been productive. A number of unique covalent coatings have emerged to manipulate the EOF and minimize protein adsorption. Of equal importance, noncovalent (dynamic) approaches have been developed which also show promise in effecting protein separations in capillaries that exhibit degradation of efficiency due to adsorption.

#### 3.3.1 Covalent Coatings

Capillaries can be functionalized (covalently coated) so that the inner walls are permanently modified. For example, a static wall coating usually consists of two chemical layers – the first reacts covalently with the silica, the outer layer being a hydrophilic neutral polymer. The polymer serves to shield residual silanol groups and increase the viscosity of the electric double layer, thus resulting in a substantial decrease, if not elimination, of EOF (Figure 2b). These coatings should be inert and resistant to degradation over a reasonably large pH range. The first material to be used as a covalent coating was polyacrylamide, a logical candidate stemming from its use in traditional slab gel electrophoresis techniques. Hjerten[20] was able to achieve near-zero EOF with polyacrylamide as the capillary coating for initial application to isoelectric focusing (IEF). Although effective, this coating suffered from stability and longevity problems.[21] Fortunately, improvements in coating procedures have minimized the problems associated with polyacrylamide coatings and commercial capillaries are now available.[9] Other, more traditional, polymer coatings including poly(vinyl pyrrolidone)[16] and poly(ethylene glycol)[22] have been employed for protein separation. In addition, a number of commercial capillaries have proved to be successful for CE-based protein separation including capillaries from the DB-series, where the coating is some dimethylpolysiloxane (originally developed for GC; J & W Scientific), fluorocarbon-coated capillaries (J & W Scientific), capillaries with an uncharged hydrophilic coating (Beckman eCAP Neutral™), anionic coated capillaries (CE-100-SA; Scientific Resources), and capillaries with a cationic coating (Celect-Amine™; Supelco). Also, as a consequence of the necessity for stable, relatively inert coatings, a number of homemade capillaries have also been found to be effective for unique protein and glycoprotein separation systems.[23–28]

#### 3.3.2 Dynamically Coated Capillaries

As an alternative to covalent passivation of the capillary surface as described in the previous section, dynamic coating of the capillary can also be carried out. This involves specific adsorption of solutes to the capillary wall, resulting in a temporary, yet stable, masking of the surface silanol groups. Depending on the nature of the dynamic coat, the negative charge imparted by the silanols is significantly reduced, eliminated, or in some cases reversed. The advantage of this approach lies in the simplicity, as it often involves nothing more
than augmenting the separation buffer with the dynamic coating additive at the appropriate concentration. As the dynamic coating is pumpable, it can be easily removed and regenerated.

3.3.2.1 Cationic Additives One approach to dynamically coating the capillary employs cationic additives some of which actually reverse EOF by changing the charge of the capillary wall from negative to positive (Figure 2c). In particular, long-chain alkyl quaternary amines (e.g. polybrene and cetyltrimethylammonium bromide (CTAB)), have been employed effectively for this purpose.\(^\text{29–33}\) The cationic head of the amine aligns with the anionic silanols on the capillary wall so that the hydrophobic tail extends into the capillary core. Unbound surfactant molecules align with their hydrophobic tails binding hydrophobically, resulting in a pseudodouble layer and a cationic wall, thus resulting in a reversal of EOF. Employing a cationic additive, separation is carried out in a pH below the pI of the protein so the positively charged proteins will be repelled by the capillary wall. This differs from dicaticionic long-chain alkyl quaternary amines (e.g. hexamethonium or decamethonium bromide) where the surface is adequately passivated without the reversal of EOF.\(^\text{34}\) Numerous reports in the literature demonstrate the success of diaminoalkane cationic additives for investigating proteins and their glycoconjugates.\(^\text{19,35,36}\)

3.3.2.2 High-salt Buffers Increasing the ionic strength of the separation buffer can also be utilized to reduce protein–wall interactions. Lauer and McManigill\(^\text{19}\) first illustrated this approach by adding potassium sulfate to their separation buffer. This prevented adsorption of standard proteins, with pI values ranging from 4.5 to 11, to the bare silica wall. Similar experiments conducted by Green and Jorgenson\(^\text{37}\) employed alkali metal salts to reduce protein adsorption. Although effective, this alternative is associated with two main disadvantages: high molar absorptivity in the low-UV (ultraviolet) region and high current resulting in increased Joule heating.\(^\text{17}\) The latter of these problems may be circumvented with the use of zwitterionic additives which can be added at molar concentrations without invoking high current with the use of high electric fields (their electroneutrality does not increase the conductivity of the buffer and creates a boundary layer of ions between the silanol layer and the proteins).\(^\text{38,39}\) The effectiveness of this approach has been illustrated by Bushey and Jorgenson\(^\text{40}\) for the resolution of basic proteins, and has since led to the use of many zwitterionic additives, including betaine,\(^\text{41}\) CAPS (3-cyclohexylamino-1-propanesulfonic acid),\(^\text{19}\) CHES [2-(N-cyclohexylamino)ethanesulfonic acid],\(^\text{19}\) and tricine\(^\text{19}\) for the successful separation of proteins. More detail on approaches for minimizing protein–wall interactions in CE is given in a number of excellent reviews on the subject.\(^\text{9,17,42,43}\)

### 4.3 Protein Structure

An important factor involved in optimizing protein separation by CE is the protein itself. Many proteins are unstable in simple buffer solutions (precipitation, aggregation, etc.) and, consequently, solubilizing (detergents) or stabilizing agents (glycerol) must be present to maintain integrity. Where these might have a negligible effect with conventional slab gel electrophoresis, they can have significant impact on the CE separation. It is reasonable to assume that, once solubilized, proteins have an electrophoretic mobility solely dependent on charge and size. However, it is now apparent that a number of factors including, but not limited to, mass and charge contribute to a protein’s mobility. For example, the electrophoretic mobility of an analyte is affected by the surrounding environment – in particular the buffer, any additives (organic modifiers), other analytes, and the capillary wall. In addition, one must be cognizant of the fact that the net charge of the protein is the total charge contribution from amino acids, metal ions, and cofactors. However, this charge is shielded by a number of environmental factors, including attraction to counter-ions in solution. Thus, it is the effective charge of a protein which contributes to mobility in an applied field.\(^\text{44}\) The hydrodynamic radius of a protein is another important factor affecting mobility in an applied field. Kálmán et al.\(^\text{45}\) demonstrated that mutants of nuclease A with a larger hydrodynamic radius had longer migration times than those proteins with smaller radii. Thus, for protein separations it may be more accurate to describe the mechanism of electrophoresis as a function of effective net charge and hydrodynamic radius instead of simply charge and size.

### 4 PRACTICAL ASPECTS OF CAPILLARY ELECTROPHORESIS

#### 4.1 Theory

The equations governing mobility, shape of the analyte zone, resolution, efficiency, and sources of variance in electrophoresis are discussed in detail in Capillary Electrophoresis of Peptides and are therefore not addressed here. An in-depth treatment of these topics is also given by Giddings.\(^\text{46}\)

#### 4.2 Separation Parameters

With the numerous parameters that must be addressed when developing a method or optimizing a CE separation, it is imperative to have an understanding of the
interdependence of one parameter with another. For example, a protein separation can be profoundly affected by slight changes in the capillary dimensions. Specifically, if closely migrating species (e.g., protein glycoforms) are not adequately resolved, increasing the capillary length will increase resolution by affording a longer on-capillary time. However, a longer capillary is associated with increased analysis times which may become unfavorable with rapid separation schemes. Fortunately, increasing the capillary length decreases the electric field strength at constant voltage, thus allowing the application of higher electric fields (usually characterized by decreased migration time). Increasing the capillary diameter has advantages and disadvantages. An increase in capillary inner diameter will improve detection sensitivity by increasing the pathlength. However, a decreased surface-to-volume ratio accompanies an increased diameter, ultimately resulting in less efficient heat dissipation which is characterized by band broadening. It is important to note that these and other parameters (such as pH, EOF, field strength, etc.) can be effectively optimized to achieve separation conditions. An evaluation of the relationship of CE variables is given in a review by Oda and Landers. Discussion is restricted in this text to only fundamental separation parameters.

4.3 Electrode Polarity

Determining the electrode polarity is of paramount importance to achieving a desired separation. Manipulation of the EOF via electrode polarity or capillary wall charge modification (through the use of coatings) enables selection of the analytes migrating toward the detector. As discussed earlier, normal polarity in a bare silica capillary is associated with an anodic inlet and a cathodic outlet. Here, positively charged species will move with the EOF and a characteristic mobility (based on charge and size) in the direction of the detector. Neutral analytes having no electrophoretic mobility will be carried with the EOF. In this system, negatively charged species will have an intrinsic mobility toward the inlet, therefore, away from the detector. However, the EOF is usually the dominating force (greater than electrophoretic mobility), thus allowing for separation and detection of anodically mobile analytes. In comparison, if the reverse polarity is set, the EOF will be in the opposite direction, away from the detector. In this case, positively charged analytes have a characteristic mobility toward the inlet (cathode) while neutral species are carried with the EOF in this same direction. Consequently, only negatively charged analytes with a mobility greater than the EOF will reach the detector. Reverse polarity is often employed when a coated capillary is used to separate negatively charged analytes or with substances that reverse the net charge of the capillary wall.

4.4 Injection

Regardless of the mode of CE utilized for separation, there are three primary methods for sample injection into the capillary: hydrodynamic, hydrostatic (by siphoning), or electrokinetic. Hydrodynamic injection is accomplished by immersing the capillary inlet into the sample and either pressurizing the sample vial or applying a vacuum to the outlet. Hydrostatic sample injection (by gravity), more common in noncommercial instruments, relies on siphoning of the sample into the capillary by elevating the sample vial relative to the outlet vial. Electrokinetic injection is accomplished by immersing the capillary inlet into the sample and, with the outlet in buffer, applying a low voltage to the system. This injection method is discriminating in that movement of the sample into the capillary depends on electrophoretic mobility and EOF. Consequently, components of the sample matrix with high electrophoretic mobility will be more likely than those with a lower mobility to be introduced into the capillary. The advantages of biased injection are discussed in detail in Capillary Electrophoresis of Peptides.

4.5 Capillary

The condition of the capillary has a substantial impact on the efficiency and reproducibility of a CE separation. This is particularly true when dealing with coated capillaries. Both the fused silica and coated capillaries can be purchased from a number of companies; however, treatment of the capillary prior to, during, and after an electrophoretic separation is crucial.

4.5.1 Conditioning

When using a new capillary or changing to a new buffer system the capillary must be conditioned. A typical conditioning procedure for a bare silica capillary is a 5–10 column volume rinse with 100 mM NaOH, followed by a 5–10 column volume rinse with water and, finally, a 3–5 column volume rinse with separation buffer. If the capillary is coated, conditioning should be performed as per the manufacturer’s protocol.

4.5.2 Regeneration

Maintenance of the capillary surface is necessary for achieving reproducible results which are largely dependent on consistent EOF. However, during the course of a separation and, particularly after multiple separations, the surface may become fouled by the sample. For this reason, the capillary surface must be cleansed of any adsorbed species (i.e., regenerated) after each separation. For a bare silica capillary and neutral or basic buffer system, regeneration is typically achieved by rinsing 3–5 column volumes with 100 mM NaOH followed
Figure 4 A step-wise approach to method development for the analysis of proteins by CE; leff is the effective length, $T = \text{temperature}$ and EK = electrokinetic.

4.6 Method Development

The development of CE methods is as idiosyncratic in nature as with HPLC. Even slight heterology in the primary structure or differences in the secondary or tertiary structure of proteins (single amino acid substitution) can require dramatic changes in methodology. Consequently, separation conditions must be unique to the system of interest. Figure 4 illustrates a step-wise approach to designing a method for protein separation by CE.

5 SEPARATION METHODS

5.1 Capillary Zone Electrophoresis

CZE is the simplest form of CE and is the mode described in most of the previous discussion. With this technique, the capillary is filled with buffer, the sample injected, the separation voltage applied to the capillary reservoirs, and the charged species within the field move toward
the opposite electrodes with their movement dependent on both charge and size (Figure 5a). Here, EOF is fundamental, allowing for the separation of positively charged, negatively charged, and neutral or uncharged species. However, situations may arise when EOF is undesirable and the inherent electrophoretic mobility of the protein of interest is of sufficient magnitude to reach the detector.

5.1.1 Proteins and Glycoproteins

The separating power of CZE has been demonstrated for a number of proteins. Early separations by Nielson et al.\(^{68}\) highlight the utility of the technique for separation of the desamido and didesamido forms of human growth hormone (hGH). To limit protein–wall interactions, the pH was raised to 8.0, well above the pI of growth hormone.
the hGH which is 5.2. More recently, CZE with LIF detection has been used to separate and detect green fluorescent protein (GFP) and GFP antibody complexes. Using a bare silica capillary and a borate buffer (pH 8.5), Korf et al.\(^{49}\) successfully separated the two forms of GFP (GFP-1 and GFP-2). Implementing CE/LIF, a six order of magnitude increase in detection sensitivity (over conventional methods) was achieved. This allowed for detection of GFP in the attomolar range. In addition, GFP was separated from GFP-complexed antibody. This presents the possibility of using CE for rapid screening of anti-GFP antibodies. Hiraoka et al.\(^{50}\) demonstrated the utility of CZE for the rapid separation of β-trace protein (βTP), a low-molecular-weight protein synthesized in the central nervous system (CNS). βTP was clearly determined in all of the samples, and internal standard quantitation was possible using an allylamine. The results indicate that βTP is nonspecifically increased in organic diseases of the CNS, especially those associated with severe physical damage to the brain tissues (such as multiple sclerosis and cerebral infarction).

It was previously not appreciated that many proteins contained glycan structures, making them difficult to separate. Tiselius\(^{33}\) offered proof of this complex structure showing that some proteins migrated as broad zones. Since then, the resolution of individual glycoforms has been achieved in several laboratories. Kilar and Hjörtén\(^{51}\) were among the first to report successful separation of glycoforms differing by a single charge. Using a static polyacrylamide coating and a buffer system composed of Tris/borate/EDTA (ethylenediaminetetraacetic acid) the glycoforms of purified transferrin (Tf) were resolved. Not long to follow were CE-based separations of the glycoprotein human erythropoietin (rHuEPO), whose primary function is to promote and stimulate the production of red blood cells. Tran et al.\(^{52}\) experimented with various buffer systems, organic modifiers, and a variety of pH regions revealing the effects of optimal buffer selection for glycoform analysis using CE. This concept of condition optimization using additives or pH modification applied to the separation of a number of glycoproteins. Almost simultaneously, Landers et al.\(^{53}\) and Traverna et al.\(^{35}\) examined the utility of borate complexation with a diaminoalkane for the resolution of glycoprotein isoforms. Using 50 mM phosphate (pH 9.0) or 100 mM borate (pH 6–10) Landers et al.\(^{54}\) partially separated five glycoforms of ovalbumin. Addition of diaminobutane (DAB) to the borate buffer (pH 8–9) appeared to slow the EOF and allowed for the resolution of 9–12 glycoforms in a purified preparation. Traverna et al.\(^{35}\) found that recombinant tissue plasminogen activator (rtPA) glycoforms were poorly resolved in coated or bare silica capillaries using a 100 mM phosphate buffer (pH 3.6). In an effort to enhance the separation, DAB was added to a number of buffers at varying pHs to examine effects on glycoform resolution. The addition of DAB to a borate buffer (pH 8.5–10) was not effective for achieving improved resolution of the rtPA; however, a tricine–DAB buffer resulted in an improved separation. DAB was not efficient with the borate buffer because the highly sialylated glycoprotein cannot effectively complex with borate. This prevents the ionic borate–DAB interaction which appears to be necessary for the resolution of glycoforms. More recently, Watson and Yao\(^{55}\) employed an uncoated capillary and a buffer containing 10 mM tricine/10 mM NaCl/2.5 mM DAB to partially resolve five peaks of erythropoietin. Addition of urea to the separation buffer allowed for the resolution of six peaks. The isoforms were identified by individually spiking with characterized sialoforms. Similar conditions to those employed by Landers et al.\(^{53}\) were employed by Morbeck et al.\(^{56}\) to separate the glycoforms of the hormone human chorionic gonadotropin (hCG). A 25 mM borate buffer containing 5 mM diaminopropane was used to separate the eight glycoforms of native hCG. The distribution of glycoforms was found to vary when hCG was purified from patients with choriocarcinoma, thus highlighting the potential of capillary electrophoretic separations for diagnostic and screening purposes. Although effective for resolving the complex heterogeneity of a number of glycoproteins, the mechanistic role of diaminoalkanes in improving the resolution of CE separations is still under investigation. Preliminary results indicate that the mechanism through which DAB and other similar additives effect resolution of glycoforms may involve more than slowing the EOF.\(^{57,58}\)

### 5.1.2 Clinical Applications

As a result of its speed, efficiency and miserly use of reagents and sample, CE has begun to gain momentum as an acceptable analytical technique in the clinical laboratory for both routine and esoteric diagnostic analyses. For example, hemoglobin (Hb) analysis is important because mutations in the protein chains induce variations in structure and impair their oxygen carrying ability. Variants of Hb, typically detected by agarose and IEF gel electrophoresis, have been shown to be analyzed effectively with a single CE analysis. Ong et al.\(^{59}\) were able to separate the components in hemolysates from normal individuals and those thought to have thalassemia. A high pH phosphate buffer was used to achieve separation of these proteins in less than 8 min. Klein and Jolliff\(^{60}\) used a near-neutral buffer to separate globin variants A2, A1, A, S, and C. Under these conditions, dramatically different profiles were found for a number of Hbs. Others have used CE technology to analyze
purified globin chains in a substantially decreased time frame from that obtained using paper chromatography or HPLC. Both Ishioka et al.\(^{61}\) and Ross et al.\(^{62}\) have applied this approach to rapid screening of globin chain and Hb variants.

CE has also been shown to be applicable to the analysis of serum proteins. Since Chen et al.\(^{63}\) proposed CZE as a viable alternative to agarose gel electrophoresis (AGE), a number of studies have been carried out showing the superiority of CE to conventional cellulose acetate electrophoresis (CAE) or AGE methods.\(^{64–66}\) Clark et al.\(^{67}\) and Katzmann et al.\(^{68}\) compared the effectiveness of CAE, AGE, and CE for the detection of monoclonal proteins in serum. Using a bare silica capillary and borate buffer, separation was achieved in 120 s and clear differences in abnormal and normal monoclonal profiles were observed. Clark et al.\(^{67}\) concluded that qualitative results obtained by CZE were comparable or better than those obtained using the gel electrophoresis counterpart. In particular, CE provided a clear advantage over gel techniques for determining the presence of a monoclonal protein for two reasons: first, precipitation is not a problem in CE and, second, in CE, the point of detection is unaffected by the point of injection. In comparison, Katzmann et al.\(^{68}\) focused more on the quantitative aspects between AGE and CE. In this study, details concerning sensitivity, specificity, and quantitation were evaluated and discussed. Jolliff and Blessum\(^{69}\) recently conducted a study comparing results of serum protein analysis by AGE and CE. It was determined that CE exhibited superior reproducibility over AGE methodology. This was attributed to protein detection using direct UV detection compared to conventional staining techniques. In a more comprehensive study conducted by Katzmann et al.\(^{70}\) sera from more than 1300 patients was examined using both conventional AGE and CE (Figure 6). CE was superior to AGE for the detection of serum abnormalities including polyclonal increases in immunoglobulin, point of application artifacts, \(\beta\)-region abnormalities, and, finally, the presence of free light chains. In many instances, sera identified as normal using conventional techniques was shown by CE to be abnormal. More comprehensive overviews of serum protein analysis via CZE are available.\(^{64,65,71–73}\)

In retrospect, serum protein analysis was an interesting challenge for CE in light of the complex nature of this matrix, the diverse character of the proteins, and their high concentration in serum. The high-pH approach (pH 9.8–10.2) works extremely well with serum where the serum sample can be injected neat (undiluted) without any sign of fouling the capillary. This is, no doubt, a function of the basic separation buffer as well as the between-run capillary regeneration with 1.0 M NaOH. Although there is a long-standing concern about the longevity and integrity of capillaries repeatedly exposed to these extreme conditions, the reproducible use of the same capillary for analysis of 20–30 serum samples daily for months without any indication of performance degradation has been observed. This speaks volumes for the ruggedness and robust nature of CE for the analysis of crude mixtures.

![Figure 6](image-url) Detection and identification of monoclonal proteins by AGE and CE. An abnormal serum sample with a monoclonal peak in the \(\gamma\)-region (indicated by the arrow) was separated and analyzed using AGE and CE. AGE was performed on a Helena REP system using the REP SPE-30 agarose gels visualized with Ponceau S Stain. Peaks were calculated using the Helena ECD scanner and software designed for the multilane agarose clinical gels (Helena Laboratories, Beaumont, Texas). CE was performed on a Beckman Paragon CZE 2000 system using Beckman system buffers, the automated sample handling module and Beckman software designed for the seven-capillary clinical instrument (Beckman Instruments, Brea, California). Immunosubtraction (IS) was performed to determine the identity of the spike. Subtraction with anti-\(\kappa\), anti-\(\lambda\), and anti-IgG reagents removed the M-spike (panels b, c and d respectively). The anti-IgA and IgM (panels e and f) reagents had little effect. (Taken with permission from ref. 70.)
In addition, CE has been applied to the analysis of urine proteins. Urinalysis has wide clinical significance, particularly because abnormal patterns are seen in many pathological conditions including various renal disorders and light chain disease.\(^{74–77}\) It was initially thought that urinary proteins, which originate from serum protein and have a similar pattern and distribution, could easily be analyzed by CE. However, a number of problems were encountered including interference from other compounds at the wavelength of detection, capillary overloading due to variability in sample protein concentration, and heterogeneous migration times. Early attempts by Chen et al.\(^{78}\) to separate and identify urine proteins by CE involved the use of a dialysis membrane with a molecular mass cut-off at 14 kDa. The dialysate was electrophoresed using UV detection at 214 or 254 nm. However, a large number of peaks from small molecules and protein breakdown products were present. Jenkins et al.\(^{79}\) evaluated the correlation between CE and high-resolution agarose gel electrophoresis (HRAGE) for the quantitation of Bence Jones protein (BJ) and albumin, both important in assessing patients with multiple myeloma. Using CE, identification and determination of migration times for a number of urine proteins was achieved. In addition, good correlation (0.93 for albumin and 0.95 for BJ) was found between CE and HRAGE. Shihabi\(^{80}\) used CE to separate and quantitate myoglobin, a protein found in patients with disorders reflecting muscle tissue breakdown including burns and trauma infections. The analysis of myoglobin in urine appears simple but is difficult for two reasons: Hb, the main pigment protein in urine, can interfere with myoglobin detection; and myoglobin denatures rapidly (within a few hours) in urine. Using an uncoated capillary and a borate buffer, separation of myoglobin and Hb was achieved in less than 7 min. Similar to many CE analyses, addition of the buffer additive poly(ethylene glycol) improved the separation by providing a sieving matrix and limiting protein–wall interactions. Friedberg and Shihabi\(^{81}\) also showed detection of urine proteins at 214 nm can be achieved by using either a wash step or cold ethanol precipitation to eliminate many interferences, whereas Oda et al.\(^{82}\) demonstrated the utility of CE for identifying the presence of monoclonal proteins in urine. In a study of more than 200 patients, diagnostic information obtained by CE was comparable to AGE. More recently, Jenkins\(^{83}\) demonstrated CE analysis of unconcentrated urine using a bare fused silica capillary where protein concentrations as low as 0.004 g L\(^{-1}\) could be detected (Figure 7). Under these conditions, BJ, intact immunoglobulin, and Tamm Horsfall protein, were separated and identified. In addition, electropherograms similar to those obtained using concentrated urine were obtained, thus eliminating the expense and time consumed for concentration procedures.

### 5.2 Capillary Gel Electrophoresis

Although one might expect that denaturing separations of proteins in sieving matrices should be easily extrapolated
from the gel format to the capillary, this has not been trivial. In fact, generating cross-linked polymer matrices or chemical gels (such as cross-linked polyacrylamide) in capillaries was difficult and suffered from technical and longevity problems. This inadequacy was solved with physical gels or pumpable polymer networks using polymers that were soluble, had low viscosity and were noncross-linked. The successful implementation of physical gels for use in DNA separations provided the format for denaturing protein analysis in capillaries. This involves standard heat denaturation of the protein in the presence of surfactant, such as sodium dodecyl sulfate (SDS), and separating in a sieving matrix such that separation is dependent on the molecular mass. Typically, the capillary is coated to eliminate EOF and is filled with a polymer sieving matrix buffer. The sample is then introduced either electrokinetically or via pressure injection under an applied electric field. As the proteins are SDS coated and hence negatively charged, they have anodic mobility and the separation must be carried out using reverse polarity (Figure 5b). CE has begun to gain popularity for molecular weight determination of proteins but still possesses some limitations.

5.2.1 Denaturing Analysis of Proteins

SDS/PAGE (sodium dodecyl sulfate polyacrylamide gel electrophoresis) separation of proteins was first reported by Hjerten\(^84\) who was able to separate human serum proteins using polyacrylamide as a sieving medium. Early work in this field was also carried by Cohen and Karger\(^85\) who demonstrated the utility of SDS/PAGE for separation of myoglobin fragments and a number of standard proteins. These and other CE separations were performed using cross-linked acrylamide as the chemical gel, which has been found to provide high resolution separation of low-molecular-weight biopolymers. However, several problems with the chemical gel-filled capillaries were realized. For instance, polyacrylamide absorbs at low-UV wavelengths, increasing the difficulty of high-sensitivity detection. Also, as a result of the rigidity of the gel, the lifetime of the capillary suffered. For example, Tsuji\(^86\) found that, with a linear polyacrylamide gel-filled capillary, only a few runs were possible before the capillary had to be replaced. Although longevity was improved by the addition of ethylene glycol, the short capillary lifetime remains a major obstacle in implementing chemical gel-filled polymers for use in CE. Consequently, a search for a replacement for these permanent gels was undertaken.

Low-viscosity physical gels which are replaced after each run have become increasingly popular for CE and can be used as noncross-linked polymer networks for the separation of high-molecular-weight SDS–protein complexes. Ganzler et al.\(^87\) showed successful separation of SDS–protein complexes, ranging in molecular weight from 17 to 206 kDa using polymer networks and low-UV detection. With the polymer gel replaced after every run, a minimum of 300 separations were performed in the same capillary without a detectable loss in resolution. Shieh et al.\(^88\) demonstrated the reproducibility and stability of capillary SDS–protein separations with seven protein mixtures that were separated in 15 min with less than 2% RSD (corrected migration time) in run-to-run and day-to-day reproducibility. Vecchione et al.\(^89\) used denaturing CE conditions to separate platelet membranes from normal individuals and those with Glanzmann thrombasthenia (GT), a hemorrhagic defect. In this study, the glycoproteins IIb and IIIa, which form heterodimers allowing for platelet–platelet cohesion, were analyzed. Using an eCAP SDS 14–200 fused silica capillary (Beckman) and reverse polarity, separation was achieved in less than 30 min. Healthy controls consistently showed the presence of glycoprotein IIb and IIIa, whereas these peaks were absent from electropherograms obtained from infected patients. Manabe et al.\(^90\) employed linear polyacrylamide as a sieving matrix for separation of SDS-complexed plasma proteins. Here the effects of the buffer composition, concentration of the sieving matrix, and sample solution composition were examined. In addition, high-resolution size separation of SDS-complexed proteins was achieved. Major plasma proteins, including albumin, IgG, and Tf, were identified from their known molecular masses. Also, linear polyacrylamide capillary electrophoresis (LPA/CE) analysis of IgG myeloma sera revealed extremely high values of IgG, suggesting the methodology may be useful in screening serum samples. SDS/CE is useful for the analysis of proteins with a large affinity for adsorption to surfaces. This has been demonstrated for the separation of fibronectin (FN), a cellular adhesion protein with a relative molecular mass (M_r) of about 400 kDa. Employing SDS denaturing conditions, the separation of FN from a series of protein standards was achieved (Figure 8).

The pharmaceutical/biotechnology industry was quick to recognize the potential for CE as a rapid quality control process. CE is especially attractive because it combines the quantification benefits of HPLC with the separating power of conventional gel techniques.\(^91,92\) SDS/CE has been compared to conventional gel SDS techniques (SDS/PAGE) for in-process control of antithrombin III (ATIII) and human clotting factor IX (FIX). In the case of ATIII, SDS/CE showed results comparable with conventional techniques with the advantage of a shorter analysis time. SDS/CE also gave similar results for FIX but was less sensitive for detection of low-concentration proteins.
5.2.2 Nondenaturing Gel-based Analyses

In addition to denaturing protein separations, CGE can also be utilized for nondenaturing protein separations. For instance, Oda et al.\(^{(93)}\) and Prasad et al.\(^{(94)}\) have developed a separation method using borate buffer with a cellulose-based sieving matrix to allow for baseline resolution of Tf glycoforms. Of particular interest to these researchers is a region known to contain carbohydrate deficient transferrin (CDTf), Tf containing less sialic acid (and carbohydrate) than the tetrasialotransferrin found as a dominant form in normal individuals. The serum Tf glycoform distribution is affected by a number of pathological states. Included in these are carbohydrate deficient glycoprotein syndrome (CDGS), a pathological condition where the cellular machinery for protein glycosylation is defective. This disease manifests itself as a neurological disorder and is characterized by an increase in the CDTf (which is composed of the di-, mono-, and asialoforms) level. Chronic, excessive alcohol abuse has also been linked to an increase in CDTf levels in serum and, therefore, presents the possibility of monitoring excessive alcohol abuse using this methodology.\(^{(95)}\) More recently, Trout et al.\(^{(96)}\) have improved this assay for the analysis of CDTf in neat serum, circumventing the need for immunopurification. Using an FC-coated capillary to slow EOF and a borate buffer system, Tf sialoforms are resolved with the direct injection of diluted serum, allowing for resolution and identification of both normal and abnormal (alcoholic) Tf glycoform patterns (Figure 9). This presents the possibility for the rapid testing of compliance in both alcohol treatment and liver transplant clinics.

It is important to bear in mind that results obtained with the use of physical gel-filled capillaries can be influenced by capillary temperature. Guttman et al.\(^{(97)}\) found dramatically different temperature effects with two different sieving matrices, poly(ethylene oxide) (PEO) and dextran. At elevated temperatures dextran chains are able to orient, through polymer–polymer interaction, into channel-like structures which yielded better resolution compared to that achieved at room temperature. The opposite effect was observed with PEO.

5.2.3 Ferguson Plots

Proteins undergoing post-translational modification, such as the addition of carbohydrates or lipids, do not bind SDS in the same ratio observed with unmodified proteins (1.4 g SDS per gram of protein). Consequently, gel-based molecular weight determination is often inaccurate due the lower charge to mass ratios, i.e. the molecular mass is overestimated. Ferguson\(^{(98)}\) developed a method to correct for the variability in SDS binding which involves determining the mobilities of standard proteins
Figure 9  Separation of (a) normal and (b) alcoholic human serum Tf using CZE. Using an FC-coated capillary (J & W Scientific) and a buffer containing a polymer sieving matrix (0.5% hydroxyethyl cellulose) separation of Tf glycoforms is achieved in less than 25 min. The nonalcoholic serum profile has normal concentrations of the sialoforms in the CDTf region. In comparison, elevated concentrations of the disialoform and the presence of asialo-Tf are seen in the alcoholic profile. The peaks are 0, asialoform; 2, disialoform; 3, trisialoform; 4, tetrasialoform.

at several different gel concentrations. The slope of an initial plot of the log of reciprocal migration time versus gel concentration gives the negative of the retardation coefficient $k_r$. A second plot (log molecular weight as a function of $k_r$) yields a more universal calibration curve. Performing Ferguson analysis using multiple slab gels at different acrylamide concentrations has obvious disadvantages – the advantage of translating this analysis to CE with replaceable gels and an automated format is clear. Werner et al. demonstrated this with a variety of proteins including $\alpha$-lactalbumin. In most cases, Ferguson plots yielded better molecular weight estimates than SDS/PAGE. It is important to remember, however, that although abnormal charge-to-mass ratios are accounted for, abnormal protein shapes are not.

5.3  Capillary Isoelectric Focusing

IEF is an equilibrium protein separation technique that relies on the establishment of a pH gradient in the gel. Unlike density gradient centrifugation and gradient gel electrophoresis, which separate based on size or density, IEF separates molecules based on their pI. By establishing a pH gradient, molecules will migrate to the zone at which the pH is equal to their pI, i.e. their net charge is zero (Figure 5c). If diffusion occurs to any extent, the molecule enters a region with a different pH resulting in the analyte acquiring a charge and electromigrating back into the focused zone. As a result of a mechanism where electrophoretic migration counters diffusional effects (as long as voltage is applied to the system), IEF has enormous resolving power.

The analysis of polypeptides has been the most prominent application of this focusing technique, particularly for determining pIs of proteins, characterizing biological fluids and monitoring protein purification. IEF has also been exploited for the analysis of glycoform microheterogeneity and resolution of charge variants.

5.3.1  Technical Considerations

Consideration of the sample matrix is an integral component in developing CIEF methods. Attention must then be paid to selection of appropriate ampholytes, adjustment of salt concentration, and dilution or concentration of the protein sample if necessary.

Broad-range ampholytes (pH 3–10) are generally used for protein mixtures with a wide spectrum of pIs, whereas narrow-range ampholytes (pH 5–8) are utilized to achieve increased resolution. It is unfortunate that the very mechanism of separation (an ampholyte-based pH gradient) masquerades as one of the obstacles in CIEF protein separations. Specifically, ampholytes (essentially polypeptides) absorb UV radiation at 200 nm which, for protein separations, is the ideal wavelength of detection. Consequently, CIEF requires detection at 254 or 280 nm which results in a substantial decrease in sensitivity for protein analyses.
With respect to salt concentration, several problems are encountered when the sample salt concentration is too high. For example, increased current due to high ionic strength, loss of resolution and gradient compression during focusing are all complications associated with high salt concentration. Consequently, samples with salt concentrations higher than 50 mM should be desalted by dialysis, gel filtration or ultrafiltration prior to focusing. A companion problem associated with high sample concentrations is protein precipitation, which is a combined function of the high protein concentrations used in CIEF and the decreased solubility of individual proteins at their pI. For example, in addition to capillary occlusion, protein precipitation can result in irreproducible migration times, current instability and slow mobilization. To counteract these consequences, detergents such as urea are often employed as additives to increase the solubility of proteins. Non-ionic detergents including Triton® X-100 and Nonidet P-40, and zwitterionic detergents such as CHAPS (3-[3-cholamidopropyl]dimethylammonio]-1-propane sulfonate) are the most commonly employed solubilizing agents.  

To detect the protein zones, mobilization past the detector must be initiated. This can be achieved in a number of ways. Single-step CIEF uses EOF to transport the focused zones past the detector. Although EOF mobilization allows for more rapid analysis times than the two-step method, the loss of resolution and complications in relating the migration time to the pI have resulted in the two-step method remaining the most common approach to CIEF. In two-step CIEF, the protein bands are focused to steady state as described earlier. Coated capillaries are used to reduce the magnitude of the EOF so that the zones are not mobilized prior to the completion of focusing. Transport of the focused zones by the detector can then be performed by several different mechanisms including chemical and hydraulic mobilization. In chemical mobilization, the application of voltage is terminated after focusing is complete and the analyte or catholyte is replaced with mobilization reagent. An electric field is reapplied to facilitate mobilization. Neutral salts, such as sodium chloride, are the most common means of achieving chemical mobilization. Sodium serves as the nonproton cation in anodic mobilization and chloride as the nonhydroxyl anion in cathodic mobilization.  

An alternative is hydraulic mobilization which utilizes the application of pressure or vacuum to mobilize the focused protein zones past the detector. It is necessary to apply an electric field to the capillary simultaneously to decrease the diffusion of the protein zones and, hence, loss of resolution during hydraulic mobilization. The disadvantage of using this method of mobilization is that the parabolic shape of the hydrodynamic flow can decrease resolution. To minimize this effect, only weak forces are used. Chemical mobilization generally produces sharper peaks for the basic proteins whereas hydraulic mobilization increases the efficiency of mobilizing acidic proteins. In addition, chemical mobilization provides much better linearity when plotting migration time versus pI, as well as better reproducibility than its hydraulic counterpart.

5.3.2 Protein Isoelectric Focusing in Capillaries

CIEF is useful for analyzing proteins that, due to amino acid mutation, post-translational modification, or the binding of metals, have extremely small differences in pI. For example, CIEF has been utilized to resolve HbA (adult hemoglobin) and HbF (fetal hemoglobin) as well as abnormal Hb variants differing only by a single point mutation in the Hb gene. Zhu et al. demonstrated the separation of Hb A and F, and variants S and C (associated with various thalassemias). Although analysis times were somewhat lengthy (approximately 13 min), remarkable resolution of the globin chains was achieved. With an unorthodox approach, Yowell et al. showed promising results focusing protein at the detector end of the capillary, significantly reducing the analysis time. In addition, Zhu et al. also showed the utility of CIEF for separation of Hb A, B, and, variants S and C associated with Bart’s disease, another potentially lethal hematological disorder. Hempe and Carver examined CIEF for use in Hb-variant screening. Using conditions that provided separation in less than 15 min for rapid turnaround times in a clinical setting, they obtained quantitative data on Hb variants and identified several rare Hb types using CIEF. The quantitative results agreed well with conventional methods, thus confirming the utility of CIEF for routine assays. Hempe et al. recently improved this assay by limiting capillary exposure to NaOH, consequently increasing capillary lifetime. In addition, improvements in the between-run reproducibility (9.6% RSD using the original method) enhance the quantitation precision. Using this novel methodology, diagnosis of HB s/β+ thalassemia is possible in one analysis (Figure 10). Conventional clinical analysis methods would require at least three separate assays to make the same interpretation.

CIEF has also been exploited for the separation and characterization of monoclonal antibodies. These biomolecules are challenging to separate as a consequence of their large size, tendency to aggregate, and heterogeneity due to post-translational modifications. Analysis of monoclonal antibodies including recombinant
CAPILLARY ELECTROPHORESIS OF PROTEINS AND GLYCOPROTEINS

Figure 10 Separation of Hb variants using CIEF. Electrophoretic separation was carried out in a 27 cm × 50 µm DB-1 capillary (J & W Scientific) at 30 kV. Hydraulic mobilization was employed. Hemolysate was introduced by low pressure injection (3.5 kPa) for 10–30 s. (a) Abnormal control formulated to resemble blood with the sickle cell trait (HbS) and HbA2 (observed in patients with β-thalassemia). (b) A blood sample from a patient with HB S/β+ thalassemia. High-efficiency separation is necessary for identification of the underlying double heterozygous. Here elevated HbA2 helps differentiate potential causes of elevated red blood cell count (RBC), low Hb concentration and low mean corpuscular volume (MCV). (Taken with permission from ref. 108.)

ATIII\(^{(109)}\) and recombinant humanized monoclonal antibody HER2\(^{(110)}\) which are significant in the diagnosis of certain types of cancer, has become possible using CIEF techniques.

Kilár et al.\(^{(111)}\) have developed a unique set-up for CIEF in uncoated capillaries. With this approach, a sandwich technique is employed where the ampholytes and analytes are injected in three steps: ampholyte solution, sample, and ampholyte solution. This allows for the use of homolog or heterolog (containing both broad and narrow range) ampholytes to be used. Also possible use of the sandwich approach is the detection of proteins with pI values outside the ampholyte range. The methodology was used for separation of Hb variants from normal and diabetic patients (Figure 11). The results obtained were similar to those using other conventional techniques.

5.3.3 Glycoproteins

Another important application of CIEF methodology is its utility for interrogating glycoform microheterogeneity. Glycoproteins often display microheterogeneity as a result of qualitative and quantitative differences in the location, length and content of the carbohydrate moieties linked to the polypeptide. This becomes important not only for understanding the function of microheterogeneity in biological systems, but also in monitoring the glycosylation pattern in the development and production of protein therapeutics. CIEF has been shown to be an excellent automated and quantitative method for analysis of glycoforms when detection sensitivity is not a critical issue. An example of the potential of this application is the analysis of human rtPA, a protein that degrades blood clots and is manufactured for treatment of myocardial infarction.\(^{(112–115)}\) Although purification of rtPA is required for high-purity IEF, in some cases as many as 20 peaks persist. However, neuraminidase treatment simplifies the pattern, suggesting that the heterogeneity may be attributed to varied sialylation.\(^{(112)}\) In addition, analysis of human Tf isoforms is possible using IEF. Kilár and Hjernten\(^{(116)}\) successfully resolved the Tf glycoforms from normal individuals showing the expected di-, tri-, tetra-, penta-, and hexasialoforms. Also, Wu and Pawliszyn\(^{(117)}\) implemented IEF methodology to examine changes in the pI of Tf due to iron binding.

5.4 Affinity Electrophoresis

Affinity capillary electrophoresis (ACE) refers to the analysis of general ligand–receptor interactions and can be used to (1) determine which sample components might undergo specific complexation, (2) investigate conditions surrounding this formation, and (3) quantitatively study
Figure 11. Novel CIEF methodology for the analysis of Hb variants. Electrophoretic separation was carried out in a 67 cm × 50 µm bare silica capillary at 20 kV. Single-step mobilization was employed with a 10 mM phosphoric acid analyte and a 20 mM sodium hydroxide catholyte. A heterologue ampholyte solution was employed using both a narrow (pH 6.7–7.7) and broad (pH 3.5–10) pH range. (a) Hb variant control (Isolab) solution (1 mg mL⁻¹). (b) Hb from a normal adult (1 mg mL⁻¹). (c) Hb from a diabetic patient (1 mg mL⁻¹). (Modified with permission from ref. 111.)

the complex. ACE can therefore be used to provide both qualitative and quantitative information about molecular interactions. This is possible because the electrophoretic mobility of a free protein changes upon binding with a ligand present in the electrophoresis buffer (Figure 5d). The difference in mobility is attributed to changes in charge, conformation, or both. Thus, by measuring the migration time of the complex as a function of ligand concentration the equilibrium constant may be calculated.

Classical gel methods may be employed to study these characteristics. However, they often require the
use of radio-labeled, fluorescently labeled, or secondary reagents that can be costly and difficult to use. In contrast, the capillary format does not demand purification of receptors and requires only small amounts of sample for analysis. As a result, the binding constants for the interaction of several receptors with their respective ligands can be determined simultaneously. Other advantages of the capillary format include temperature control, free solution separations and high-speed analysis.

5.4.1 Proteins and Glycoproteins

The utility of CE for determination of binding constants was realized when the first paper describing the use of CE for protein analysis appeared in 1986. As mentioned previously, Lauer and McManigill\(^1\)\(^{118}\) found that protein migration times were retarded due to ionic interaction with the capillary wall. Thus, as many of the binding forces between proteins and ligands are ionic in nature, it was obvious these interactions could like-wise be examined. Consequently, two approaches for measuring binding constants using CE emerged – nonequilibrium and equilibrium methods. The latter of the two, commonly termed ACE, will be discussed briefly here. A comprehensive treatment of the subject is given by a number of published reviews on the subject.\(^1\)\(^{119–121}\)

ACE is an ideal technique for examining the binding of metal ions to metal-binding proteins. This results from the fact that minute changes in the charge of the protein will effect the electrophoretic mobility and, consequently, the migration time. Heegard and Robey\(^1\)\(^{122}\) examined the effects of Ca\(^{2+}\) concentration on the migration time of human C-reactive protein (CRP). They observed the expected decrease in mobility with increased ion concentration. Similar results were obtained by Kajiwara et al.\(^1\)\(^{123}\) using the proteins calmodulin and parvalbumin.

Protein–protein interactions can also be studied using CE techniques. Early work by Grossman et al.\(^1\)\(^{124}\) showed separation of antibody–antigen complexes using CE. Nielsen et al.\(^1\)\(^{125}\) extended these findings by separating free hGH and antibody from the hGH–antibody complex. Although protein–protein measurements (as a result of their size) can be accomplished by a host of other techniques which are equal or superior to ACE, this technology offers advantages when the proteins of interest are present in limited quantities.

A diagnostic test for the scrapie prion protein (PrP\(^{SC}\)) described by Kajiwara et al.\(^1\)\(^{119–121}\) is clear. The advantages driving the interest in this technology include the simplicity of a system that can provide electrophoretic protein analysis in free solution, with multimode capabilities, minimal reagent and sample requirements, high efficiencies, on-line detection, and all in an automated format. This allows for rapid definition of optimal conditions as well as experimentation with numerous modes in search of a suitable method for a particular protein(s).

Although only a fraction of the literature associated with the use of CE for protein analysis has been covered here, the growing acceptance of capillary-based analysis as an alternative to the conventional slab and tube gel formats, and as a complementary technique to HPLC, is clear. The advantages driving the interest in this technology include the simplicity of a system that can provide electrophoretic protein analysis in free solution, with multimode capabilities, minimal reagent and sample requirements, high efficiencies, on-line detection, and all in an automated format. This allows for rapid definition of optimal conditions as well as experimentation with numerous modes in search of a suitable method for a particular protein(s).

Unlike other analytes, the CE-based analysis of proteins is complicated by the predisposition of these solutes for adsorption to the capillary wall. One must, therefore, be prepared to seek a compromise between conditions ideal for the stability of the protein(s) of interest and those which minimize adsorption, so that separation efficiency is not destroyed. Capillary wall deactivation can be accomplished using a battery of approaches including covalent modification of the surface as well as dynamic deactivation. The latter is a largely
unexploited area that warrants exploration based on the simplicity of surface passivation via simple modification of the separation buffer.

It is clear that the same multimode flexibility associated with protein analysis by gel electrophoresis and HPLC is applicable to CE. Consequently, the simplicity of CE will allow for accelerated method development for applications ranging from purity characterization and microheterogeneity analysis to pI determination and clinical marker detection. As methods for protein analysis evolve, one can expect to see the development of protein CE buffer systems with improved compatibility for detectors such as MS. This will facilitate the use of hyphenated techniques such as (CE/MS),\(^\text{139}\) where CE is used as the first dimension with MS as the detector, and improve capabilities for structural identification and, ultimately, the establishment of functional properties of individual proteins and glycoproteins. The future will also see other hyphenated techniques furthered in their development where the speed of CE allows it to function as the second dimension. The pioneering work of Jorgenson’s group with the development of liquid chromatography/capillary electrophoresis (LC/CE)\(^\text{140}\) presents the possibility of revolutionizing protein analysis, especially if the two-dimensional system can be interfaced with MS as the detector. Technological advances such as these, combined with advances in method development, including capillary coating and detection, are sure to make protein analysis by CE commonplace in the future.

ABBREVIATIONS AND ACRONYMS

ACE | Affinity Capillary Electrophoresis
-- | --
AGE | Agarose Gel Electrophoresis
ATIII | Antithrombin III
BJ | Bence Jones Protein
CAE | Cellulose Acetate Electrophoresis
CDGS | Carbohydrate Deficient Glycoprotein Syndrome
CDTf | Carbohydrate Deficient Transferrin
CE | Capillary Electrophoresis
CGE | Capillary Gel Electrophoresis
CIEF | Capillary Isoelectric Focusing
CITP | Capillary Isochrochromatophoresis
CNS | Central Nervous System
CRP | C-reactive Protein
CTAB | Cetyltrimethylammonium Bromide
CZE | Capillary Zone Electrophoresis
DAB | Diaminobutane
EDTA | Ethylenediaminetetraacetic Acid
EOF | Electroosmotic Flow
FIX | Human Clotting Factor IX
FN | Fibronectin
GC | Gas Chromatography
GFP | Green Fluorescent Protein
GT | Glanzmann Thrombasthenia
Hb | Hemoglobin
HBa | Adult Hemoglobin
HbF | Fetal Hemoglobin
hCG | Human Chorionic Gonadotropin
hGH | Human Growth Hormone
HIV | Human Immunodeficiency Virus
HPLC | High-performance Liquid Chromatography
HRAGE | High-resolution Agarose Gel Electrophoresis
IEF | Isoelectric Focusing
IS | Immunosubtraction
LC/CE | Liquid Chromatography/Capillary Electrophoresis
LIF | Laser-induced Fluorescence
LPA/CE | Linear Polyacrylamide Capillary Electrophoresis
MCV | Mean Corpuscular Volume
MEKC | Micellar Electrokinetic Chromatography
Mr | Relative Molecular Mass
MS | Mass Spectrometry
OLP | Ohm’s Law Plot
PEO | Poly(ethylene oxide)
pI | Isoelectric Point
PrPsc | Scrapie Prion Protein
RBC | Red Blood cell Count
rHuEPO | Human Erythropoietin
RSD | Relative Standard Deviation
rtPA | Recombinant Tissue Plasminogen Activator
SDS | Sodium Dodecyl Sulfate
SDS/PAGE | Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis
Tf | Transferrin
βTP | β-trace Protein
TSE | Transmissible Spongiform Encephalopathy
UV | Ultraviolet
UV/VIS | Ultraviolet/visible

The focus of this article is to describe the developments of capillary electrophoresis (CE) on-line with detection by mass spectrometry (MS) for the analysis of peptides and proteins. Following a brief introduction in which we discuss the increasing role of the mass spectrometer for characterizing these important biomolecules, we present a historical overview of capillary electrophoresis/mass spectrometry (CE/MS). The latter discussion describes the experiments that allowed the connection of CE with MS, through developments to increase the volumes of analyte solutions that can be analyzed, to the current investigations of microfabricated chips that bring CE/MS towards a nanoscale technology. We also consider the technical aspects of CE/MS, which include how to inject analyte mixtures into the capillary, ways to improve the concentration sensitivity of the technique, the optimal capillary surface technology to use, and considerations of buffer compositions that are compatible with on-line MS detection. Other practical issues, including the physical connection between the CE and MS components, along with sample preparation and sequencing peptides by this technology are also reviewed. In the final section, the future of CE/MS is contemplated, with particular emphasis on the current developments of nanotechnologies that include the interfacing of microchip-based CE with MS.

1 INTRODUCTION

The use of MS in the biomedical sciences has experienced rapid growth in recent years. This can be attributed to the development of technology [such as electrospray ionization (ESI)] that allows the rapid and cost-effective analysis of many thermally labile, hydrophilic molecules. Protein analysis, peptide mapping, and peptide sequencing at concentrations compatible with extracted amounts from biological systems by MS is a current area of continuous improvement. This has accelerated developments in proteomic research, in which proteinaceous products of expressed genes are rapidly mapped.

Many MS strategies are evolving for sequencing of peptides and proteins. These include the use of micro- and nanospray technologies that allow low-flow infusion of analyte mixtures, and a more efficient utilization of precious samples. This overcomes one of the main limitations of the scanning mass spectrometer, which is the acquisition of acceptable ion statistics for compounds of low transience in the instrument. High scan speeds usually correlate with reduced MS sensitivity. Prolonged persistence of molecules of interest within the mass spectrometer permits the use of slower scan speeds and a concomitant increase in sensitivity is observed. However, these techniques are not without limitations. In particular, ion suppression results in the detection of one species in preference to another. An inability to detect and characterize an analyte of interest (e.g. a phosphorylated peptide) may result when such molecule is a minor component of a complex mixture. This situation can often be overcome by separation of the components of the analyte mixture using chromatography on-line.
with the mass spectrometer. In this regard, the coupling of condensed phase chromatography [high-performance liquid chromatography (HPLC) and CE] to the mass spectrometer has been thoroughly investigated and developments have occurred to provide technologies for the analysis of many widely different complex samples.

In this article we present and review the techniques of on-line CE/MS for the analysis of peptides and proteins. Particular emphasis will be placed upon the developments that improve the robustness and sensitivity of this technology. We also review strategies that facilitate on-line manipulation of samples to effect isolation, concentration, and analysis of components of interest.

2 HISTORY

Characterized by fast analysis times, unrivalled analyte resolution and ultrahigh separation efficiencies, CE was expected to revolutionize the analysis of complex solutions of peptides and proteins. Indeed, these characteristics along with low sample consumption and in theory improved analyte recovery (and thus high sensitivity) combine to yield a very powerful analytical technology, which was further enhanced through its coupling to the mass spectrometer. Furthermore, CE offers a number of different separation mechanisms that complement traditional technologies such as HPLC. In addition to free solution separations, CE affords analyte resolution by isoelectric focusing, isotachophoresis, molecular weight sieving, and even separation according to analyte hydrophobicity by interactions with micelles [as in micellar electrokinetic chromatography (MEKC)].

Affinity capillary electrophoresis (ACE) and affinity capillary electrophoresis/mass spectrometry (ACE/MS) separations have also been developed to investigate ligand-receptor interactions, and the potential for such technology for screening combinatorial drug candidate libraries has been demonstrated. However, the development of CE and on-line CE/MS for the analysis of peptides and proteins has not been without complex challenges, and these technologies have been shown to suffer some severe limitations. First, highest analyte resolution is usually only achieved when the sample injection volume is less than 2% of the total capillary volume. Hence sample injection volumes are usually in the range of tens of nanoliters for regularly used capillaries [50 μm internal diameter (ID)] to low picoliters for small internal diameter capillaries (<10 μm ID) that have been shown to yield the best CE/MS sensitivity. The concentration sensitivity of CE (and CE/MS) is therefore significantly inferior to that of other techniques such as HPLC, which can accommodate sample injection volumes of tens to hundreds of microliters. Sample concentrations for CE and CE/MS analysis are thus often required to be exceptionally high. Typically, this is not ideal for mixtures of biologically important peptides and proteins. At high concentration, these molecules tend to denature, aggregate, and precipitate. Peptides and proteins also tend to adhere to surfaces of vials and pipet tips, which can lead to further substantial losses. Therefore, various creative approaches have been developed to enable the injection of larger sample volumes into the CE capillary. These include in-capillary electrophoretic analyte stacking and focusing, coupled capillary isotachophoresis (cITP) with CE, and various designs of analyte concentrators and membrane preconcentration (mPC) preprocessors and all of these approaches will be discussed later.

A second significant problem with CE (and CE/MS) arises from the fact that the silica surface of CE capillaries is not chemically inert. When filled with an aqueous solution, the silica surface takes on a negative charge that is dependent upon the pH of this solution. This is one of the primary contributors to the development of an electroosmotic flow (EOF) from anode to cathode. However, such anionic character also provides an active surface for, in particular, basic peptides and proteins to adsorb. In addition to these electrostatic interactions, hydrophobic interactions and the formation of hydrogen bonds between the peptide or protein and the silica capillary are also prevalent. Hence, while there are no solid particles for analytes to adsorb irreversibly, peptides and proteins are often lost to the silica surface of the CE capillary. Consequently, method sensitivity is reduced, as are analyte resolution and separation efficiency. Again, creative solutions have been developed to overcome this limitation. These include the use of buffers of extremes of pH, to suppress the ionization of the silica surface (low pH), which has been successfully used for the analysis of peptides or to ensure that analytes are anionic (high pH). Various capillary coatings have also been developed and several polymeric capillaries have been evaluated. All of these approaches will be reviewed later.

The coupling of CE on-line with MS has also not been without challenge. Here, the technology had to be considered as a whole, since the predominantly aqueous buffer used for the CE separation has been shown to influence directly the MS performance and overall method sensitivity. In addition, the interface between the CE and MS systems requires careful thought since this device has to provide both the counter electrode for the CE separation and the voltage (or ground) for the electrospray interface. While there have been a number of CE/MS interface configurations, one of the most popular is the sheath liquid interface that was first described by Smith et al. This interface is readily assembled,
and is reasonably robust.\textsuperscript{[107]} One limitation of this approach is that the sheath liquid can introduce a sizable chemical background. Miniaturization of the sheath liquid interface, so that the coaxially delivered sheath liquid is delivered at a flow rate of less than 1 µL min\textsuperscript{-1}, reduces such a background, and leads to a significantly improved signal-to-noise ratio (S/N).\textsuperscript{[108]} Subsequently, development of a sheathless interface and the coupling of CE to micro- and nanospray MS has further improved the analyte sensitivity and S/N.\textsuperscript{[82,96,109–113]} The coupling of micro-fabricated CE chips to MS in which the interface is a “pin-hole” in the side of the CE chip has also recently been evaluated.\textsuperscript{[109,114,115]} These devices show much promise for the further development of this technology for high sensitivity analysis of peptides and proteins, and they are reviewed in a later section.

3 CONSIDERATIONS FOR CAPILLARY ELECTROPHORESIS SEPARATIONS OF PEPTIDES AND PROTEINS

3.1 Sample Injection

Three modes of sample injection into the CE capillary are typically used for analyte analysis by CE with on-line MS detection. These include electrokinetic injection, during which high voltage is applied to the sample solution; analytes migrate into the capillary according to their electrophoretic mobility, and may be transported by the migration of solvated ions.\textsuperscript{[116]} This mode of injection is dramatically affected by the salt concentration of the sample matrix. The amount of analyte injected into the capillary can vary from sample to sample unless much care is taken to ensure that each sample is isotonic. Furthermore, analytes of differing charge will migrate into the capillary at different rates. Hence, this technique introduces selectivity into the analysis. For these reasons, electrokinetic injection is not usually particularly useful for the analysis of biologically derived mixtures of peptides and proteins.

The two other sample injection modes for CE/MS are based upon hydrodynamic flow. For one of these methods, the inlet of the CE capillary is immersed in the sample vial and raised, for a specific period, to a defined height above its outlet.\textsuperscript{[116]} The volume of sample injected is dependent upon the back-pressure of the capillary, the height differential between the capillary inlet and outlet, and the time of the injection. This technique is often most commonly used when a home-made CE system is connected to the mass spectrometer. For commercially available units, the CE capillary is inserted into a sealed sample vial, to which a nitrogen head pressure is applied for a specific length of time. Sample is forced from its vial into the CE capillary, in preparation for subsequent electrophoretic separation. Since both of these techniques are based upon hydrodynamic flow, all components of a complex mixture are injected into the CE capillary and there is less selectivity than observed with electrokinetic injections. However, salt from the matrix of biologically derived samples will be introduced along with analytes of interest into the capillary. This will significantly affect the performance characteristics of the separation, and this subject will be addressed in the sections that follow.

3.2 Concentration Sensitivity

Many factors affect the overall sensitivity of CE/MS. One such factor is the design of the interface and the actual coupling of the two techniques. There is also an incompatibility of the peak widths of CE responses and the scan speed of the mass spectrometer. As mentioned above, faster mass spectrometer scan speeds typically result in reduced sensitivity of the scanning mass spectrometer. This problem has been overcome using one of several methodologies. First, if the analyte is known, selected ion monitoring (SIM) can be used to continuously monitor the compound(s) of interest.\textsuperscript{[5]} Second, the type of MS detector can also play a role. For example, an array detector for a sector mass spectrometer can yield 50–100-fold more signal than a standard electron (or photon) multiplier.\textsuperscript{[117]} Reduced elution speed (RES), in which the CE voltage is substantially reduced prior to elution of the first analyte, has been developed by Smith’s group to widen CE peaks, thereby allowing the use of slower scan speeds.\textsuperscript{[118]} Separations of proteins by cITP have also been coupled with MS.\textsuperscript{[146]} This separation technique produces zones of constant protein concentration that are eluted into the mass spectrometer. This compares with a peaked response for most other separation techniques. Improved ion statistics may result. However, the development of cITP separation conditions is not as simple as free solution conditions, since buffer zones of different mobility are required to effect analyte resolution by the cITP mechanism.\textsuperscript{[16,49]} Ion trap mass spectrometry (ITMS) (quadrupole traps)\textsuperscript{[112]} and Fourier transform mass spectrometry (FTMS) (ion cyclotron resonance)\textsuperscript{[119]} instruments and fast scanning time-of-flight (TOF) systems\textsuperscript{[120]} may also afford improved sensitivity of CE/MS analyses (see later discussions).

The composition of the separation buffer (or electrolyte) and the ID of the CE capillary also affect the overall sensitivity of the CE/MS method.\textsuperscript{[104,105]} A highly conductive background electrolyte (BGE) may be used for efficient CE separations but often interferes with electrospray processes, which can lead to reduced mass spectrometer sensitivity and ion beam instabilities. In this regard, it has been shown that the smaller bore capillaries...
(<10 µm ID) lead to the highest CE/MS sensitivity.\(^{28}\)^{121}\)
The lower flow of BGE from these capillaries enables a wider variety of aqueous solutions to be used to effect analyte separations.\(^{28}\) However, the use of small-bore capillaries also exaggerates the problem of poor CE and CE/MS concentration sensitivity. Such capillaries accommodate CE analyses of only very low volumes (often low picoliters) of sample.\(^{25} - 27\)

The low internal volume of CE capillaries leads to a requirement for high analyte concentration for all CE and CE/MS studies. Analyte preconcentration can be achieved by off-line sample preparation, using lyophilization, or adsorption on a solid phase to permit both sample cleanup and analyte concentration. However, off-line manipulations of dilute solutions of peptides and proteins should be minimized, since losses to exposed surfaces (e.g., vials, pipet tips, solid phases) can be substantial. In addition the tendency for these molecules to denature, aggregate, and, ultimately, precipitate causes further analyte losses. Therefore, many investigators have attempted to improve the sample loading capacity of the CE capillary while maintaining optimal analyte resolution and separation efficiency.

Initially, a variety of electrophoretic concentration techniques, including analyte stacking,\(^{29} - 34\) field amplification\(^{35} - 45\) and transient isotachophoresis (tITP)\(^{46} - 49\) were developed to preconcentrate analytes following injection of the sample into the capillary. All of these techniques are implemented as voltage is applied across the CE capillary, and cause analyte zones to concentrate owing to different field strengths or chemical microenvironments that form within the CE capillary.\(^{116}\) Consequently, larger analyte volumes can be analyzed with minimal loss of component resolution and separation efficiency. In most favorable cases, the sample can constitute up to approximately 90% of the total CE capillary volume with minimal loss of CE performance. However, since the total capillary volume is small, maximum sample loading is usually limited to less than 1 µL. Furthermore, as mentioned above, salts in the sample matrix can disrupt such analyte stacking and focusing processes. Such matrix components introduce zones of low electric field within the capillary upon application of high voltage.\(^{27,116}\) Analyte ion migration velocities are slower, and this usually prevents the analytes focusing into discrete zones. Therefore, preprocessing of biologically derived mixtures may be required to reduce their salt concentration prior to use of these electrophoretic stacking and focusing techniques. Nevertheless, use of in particular capillary electrophoresis/transient isotachophoresis/mass spectrometry (CE/tITP/MS) has provided a means for analyte preconcentration to a sufficient level to allow its use for the analysis of peptide and protein mixtures.\(^{46}\)

A technique that emerged from single-column tITP was the use of coupled capillary isoelectric focusing/capillary electrophoresis/mass spectrometry (cIEF/CE/MS).\(^{47} - 49\) For this approach, cITP separations are performed in wide-bore (100–200 µm ID), larger volume capillaries. Following the cITP step, analytes are transferred into the CE capillary for further separation and subsequent MS detection. This technique permits the analysis of sample volumes as large as 20 µL, and as such it provides a practical means of enhancing the concentration sensitivity of CE/MS. However, this technique is significantly more complex than other strategies for concentration sensitivity enhancement, and is not particularly well suited to routine operation.

In another approach, capillary isoelectric focusing/mass spectrometry (cIEF/MS) allows the analysis of a full capillary volume of sample.\(^{11} - 15, 108, 122, 123\) This technique has proved to be particularly useful for the analysis of complex mixtures of proteins. Separations are usually performed in a coated capillary that exhibits negligible or zero EOF.\(^{115, 108, 122, 123}\) In a focusing step, ampholites, which are premixed with the sample, migrate through the capillary to form a pH gradient. Simultaneously, proteins migrate until they reach the pH zone that corresponds to their isoelectric point (pI), where they become neutral, and no longer migrate. Here, the proteins focus into discrete zones, and are preconcentrated. Ultimately, a stationary state is achieved when all proteins have migrated into the pH zones that correspond to their pI.\(^{11}\) Mobilization of the proteins into the mass spectrometer is achieved using an electrophoretic approach, hydrodynamic flow, or a combination of these techniques.\(^{11} - 15, 108, 122, 123\) While cIEF/MS has been shown to be useful for the analysis of proteins, the processes of pH gradient formation and analyte focusing are severely perturbed by salt. High salt concentrations lead to excessive currents during the focusing phase of the experiment. This causes ampholyte zone broadening and a less well-defined pH gradient. Recently, we have found that use of a 5–10 min gradient application of voltage facilitates on-line removal of salt.\(^{15}\) The current profiles observed in these experiments led us to conclude that the relatively slow application of the focusing voltage allows the ejection of highly mobile salt, as the pH gradient is developed and proteins migrate to zones that correspond to their pI. This is shown in Figure 1(a) and (b). Here, two protein solutions were analyzed using the same zero EOF, PVA-coated capillary. First, a solution containing lysozyme, cytochrome c, myoglobin, carbonic anhydrase, and trypsin inhibitor in water was analyzed using a standard cIEF approach, and the results of this analysis are shown in Figure 1(a). Subsequently, the same proteins were dissolved in water that contained 200 mM sodium chloride. Analysis of the latter solution by a
from the capillary and are replaced by counterions of the BGE. While a UV detector was used to acquire the data shown in Figure 1(a) and (b), we have subsequently demonstrated the efficacy of this approach for analysis of physiologically derived protein mixtures by cIEF/MS. It the latter study we demonstrated the detection of glycated hemoglobin chains in diabetic blood and the direct analysis of cerebral spinal fluid by cIEF/MS.124,125

Analyte concentrators and mPC devices have also been developed to overcome the relatively poor concentration limits of detection of CE and CE/MS. This technology has been the subject of three extensive reviews.27,126,127 Briefly, such technology is based upon the insertion of a small bed of adsorptive phase, multiple capillary bundle, immunoaffinity capture support or impregnated membrane at the inlet of the CE capillary (see Figure 2). Principally analytes are adsorbed on a phase to effect their concentration. Injection volumes in excess of 200 μL are routine with this technology, which corresponds to an increase in concentration sensitivity often upwards of 100–1000 times that of a conventional CE injection method. In addition, since analytes are adsorbed on a solid phase or impregnated membrane, on-line sample cleanup can be effected by washing the phase with a suitable solvent.87,88 For biologically derived peptide and protein samples, this process permits the removal of salt and other hydrophilic contaminants that interfere with the electrophoretic separation of these analytes. This eliminates the need for excessive off-line pretreatment, which improves analyte recovery, which ultimately further enhances concentration sensitivity. Some of these techniques (e.g. mPC) have also been shown to be compatible with contemporary CE stacking and focusing chemistries. Indeed, membrane preconcentration/transient isotachophoresis/capillary electrophoresis/mass spectrometry (mPC/tITP/CE/MS) has been shown to be an optimal technique for the separation and sequencing of low concentrations of peptides.86–88,96 A major consideration for optimal membrane preconcentration/capillary electrophoresis/mass spectrometry

Figure 1 Capillary isoelectric focusing (cIEF) electropherograms of a five-component protein mixture (a) in the absence of salt and (b) from a solution that was prepared in 200 mM NaCl. Both samples were diluted 1:1 with ampholyte solution. Focusing and mobilization solutions were anolyte 50:49:1 (v/v/v) methanol–water–acetic acid and catholyte 50:49:1 (v/v/v) methanol–water–ammonia solution. The desalting protocol used for (b) was a linear gradient to 10 kV in 6 min. Protein focusing was at 20 kV for ~20 min. Mobilization was at 20 kV until the experiment was complete and all of the proteins were detected. Protein detection was by ultraviolet (UV) absorbance at 280 nm. The CE capillary was 50 μm ID × 37 cm (effective length was 30 cm to the UV detector), and coated in-house with poly(vinyl alcohol) (PVA). (Reprinted with permission from J.J. Clarke, A.J. Tomlinson, G. Schomberg, S. Naylor, Anal. Chem., 69, 2786–2792 (1997). Copyright 1997, American Chemical Society.)

standard cIEF approach failed. As a voltage of 20 kV was applied to the capillary (over 30 s) to affect analyte focusing, the current rose to ~45 μA and became unstable. It was impossible to obtain satisfactory results from this system without first removing the sodium chloride by means of a slow voltage ramp, and this is demonstrated in Figure 1(b). Clearly, this technique worked well, and was, in our hands, reproducible. As expected, a small shrinkage of the pH gradient was observed. This occurred during the desalting process when cations and anions are mobilized

Figure 2 Schematic diagram of a mPC cartridge. Note the gaps in the cartridge; these are to prevent perturbation of the EOF cause by a high back-pressure in the cartridge if the membrane is compressed. Also, push-fit joints construct the cartridge.
(mPC/CE/MS) performance is the use of a sufficient volume of an elution solvent (e.g. 80% methanol or acetone in water) to ensure maximized peptide recovery. However, the use of an excessive volume of elution solvent severely degrades the separation performance of the analysis. Use of a tITP focusing strategy in conjunction with mPC tends to overcome this problem, since analytes are focused into discrete zones as voltage is applied across the capillary.86–88

The tITP condition that we developed for use in conjunction with mPC/CE/MS is shown schematically in Figure 3. In a systematic study we have shown that mechanistically this stacking/focusing regime is a complex combination of transient cIEF, tITP and analyte stacking, that needs to be fully optimized for each membrane preconcentration/capillary electrophoresis (mPC/CE) capillary used. However, once optimized this system works extremely well. This is shown in Figure 4. Here, a single reversed-phase HPLC fraction that was derived from a biological mixture of rat major histocompatibility complex (MHC) class I peptides were analyzed by mPC/tITP/CE/MS. The power of the technique is demonstrated by the resolution of isobaric peptides (see Figure 4).

We have also used this technique to identify a mouse Kb peptide that promotes T-cell maturation in the thymus. More recently, Hunt’s group also demonstrated the value of mPC/tITP/CE/MS for sequencing MHC class I peptides (see Figures 5 and 6). In this example, the mPC/CE capillary was coupled to an ITMS instrument via a novel microspray interface (see later discussions for a review of interface technology).89 Here, peptide sequencing with attomole sensitivity was demonstrated by the analysis of an immunologically active MHC class I peptide fraction that was isolated from an extract of 10^10 cells from the human melanoma tumor (DM6) cell line. Full sequence data was achieved for a known active peptide by membrane preconcentration/transient isotachophoresis/capillary electrophoresis/tandem mass spectrometry (mPC/tITP/CE/MS/MS) (see Figure 6).

While peptide analysis by mPC/tITP/CE/MS can be achieved using an uncoated fused-silica capillary and an acidic BGE, it is our experience that peptides

Figure 3 Schematic diagram of the tITP conditions that have been developed for peptide analysis by mPC/CE/MS. Typical conditions are 60 nL of each of the reagents.

Figure 4 Partial mPC/CE/MS electropherograms of rat RT1a–TAPα MHC class I peptides. The mPC cartridge contained a polymeric styrene–divinylbenzene-impregnated membrane and the CE capillary was uncoated fused silica, 25 µm ID × 70 cm. Injection volume was 50 µL. BGE was 2 mM ammonium acetate in 1% aqueous acetic acid, leading stacking buffer was 1% ammonia solution in water (60 nL), elution solvent was 80% methanol in water (60 nL), trailing stacking buffer was BGE (60 nL). Applied separation voltage was 25 kV. ESI voltage was 2.5 kV referenced to the accelerating voltage (5 kV) of a Finnigan MAT 95Q mass spectrometer. A sheath liquid interface of 60% 2-propanol in 1% aqueous acetic acid was used at 3 µL/min. Peptide detection was by an electron multiplier, instrument resolution was ~300. Scan range was 300–1300 u at 3 s per decade.
humor, we have found a polybrene-coated capillary to be beneficial for the recovery of analytes from the membrane, and overcame a selectivity problem at the lower acetonitrile concentrations. Furthermore, we demonstrated that there was no requirement for the addition of an acid to this elution solvent. Indeed, addition of 0.1% trifluoroacetic acid (TFA) to the 80% acetonitrile elution solvent had only detrimental effects on protein separation.\textsuperscript{(129)} We attributed this result to localized interaction of the TFA, an efficient ion-pair reagent, with the positively charged polybrene-coated capillary. In addition, we found that use of a less efficient ion-pair reagent (such as acetic acid) did not influence protein recovery. We attributed this result to the fact that gaps are deliberately introduced in mPC cartridges as they are prepared. This prevents perturbation of EOF by the cartridge. However, turbulent mixing of injected solvent will also occur. Thus while an elution solvent of 80% acetonitrile in water is injected into the mPC/CE capillary, proteins will be eluted from the membrane by the formation of a solvent gradient. As acetic acid is a constituent of a typical BGE for this application, the front edge of the elution solvent will be modified with this reagent. We postulate that this would tend to be beneficial for the recovery of analytes from the membrane.\textsuperscript{(129)}

Subsequent to the systematic study, we have successfully applied mPC/CE and mPC/CE/MS to the analysis of several physiological fluids, including cerebrospinal fluid (CSF), tears, and aqueous humor [see Figure 7(a) and (b)].\textsuperscript{(130)} In this example we demonstrate the use of mPC/CE/MS to allow a comparison of the composition of “normal” aqueous humor (taken from a patient undergoing cataract surgery) and that which was obtained from an individual with PEX syndrome. Several proteins have been tentatively identified from these studies, and we have found few qualitative differences in the composition of the syndrome sample and the control. One lead that we are currently pursuing is the absence of a protein of molecular weight 13 343, and its putative oxidized form (molecular weight 13 361) in the PEX sample, and these studies are on-going. During these studies, we found that protein recoveries were often poor (<25%) and irreproducible when we analyzed standard mixtures of these analytes. In contrast, the recovery of components of physiologically derived protein mixtures was much higher (>90%). We attributed this result to the presence of high salt concentrations in these later solutions that tended to modify the adsorptive properties of the C\textsubscript{8}-impregnated membrane.

From our studies it is clear that mPC/CE/MS analysis of protein mixtures is still in its infancy, being limited by the current choice of impregnated membranes. This approach will undoubtedly improve in the future as new impregnated membranes of more appropriate

and proteins are more optimally analyzed using a coated CE capillary.\textsuperscript{(128)} In our studies of MHC class I peptides, tear proteins, and the composition of aqueous humor, we have found a polybrene-coated capillary to be most suitable.\textsuperscript{(128–130)} Again, the use of a tITP strategy in conjunction with mPC/CE/MS ensures that a larger volume of an elution solvent can be used with little detriment to the separation performance. Indeed, it has been our experience that unless a relatively large volume of elution solvent is used, proteins are not efficiently recovered from currently available impregnated membranes. In a systematic study, we found that the composition of the elution solvent was critical for elution of proteins from a C\textsubscript{2}-impregnated membrane.\textsuperscript{(129)} Increasing acetonitrile concentration from 40 to 80% in water significantly improved protein recovery from the membrane, and overcame a selectivity problem at the lower acetonitrile concentrations. Furthermore, we demonstrated that there was no requirement for the addition of an acid to this elution solvent. Indeed, addition of 0.1% trifluoroacetic acid (TFA) to the 80% acetonitrile elution solvent had only detrimental effects on protein separation.\textsuperscript{(129)} We attributed this result to localized interaction of the TFA, an efficient ion-pair reagent, with the positively charged polybrene-coated capillary. In addition, we found that use of a less efficient ion-pair reagent (such as acetic acid) did not influence protein recovery. We attributed this result to the fact that gaps are deliberately introduced in mPC cartridges as they are prepared. This prevents perturbation of EOF by the cartridge. physicochemical properties (e.g. wide-pore polymeric phases such as PLRP-S 4000 Å) become available. In addition, further development of affinity capture analyte concentrators will prove to be very valuable for the isolation and analysis of target proteins.

3.3 Capillary Surface Technology

As mentioned previously, CE was initially thought to be a new approach that would revolutionize the analysis of peptides and proteins. For some applications (e.g. the sequencing of MHC class I peptides) CE has been proved to be extremely valuable. However, capillary surface technology has proved to be a major challenge for the analysis of these important biopolymers. Indeed, manufacture of fused-silica capillaries that exhibit constant surface properties has been the subject of much industrial research by companies that supply this consumable to the users of CE. In our own hands, we have found that while a CE capillary that is prepared from a bulk supply may provide high performance, the next length of fused-silica may not condition at all. In addition, there is no way of predicting in advance which piece of fused-silica will work, and this can be both frustrating and time-consuming. For peptides and proteins, capillary preparation is further complicated by potential analyte–wall interactions. As noted above, the internal surface of a fused-silica capillary is ionized when filled with an aqueous BGE. While the degree of ionization is dependent upon the pH of the BGE, the ionized silanol groups of the CE capillary provide an active anionic surface to which peptides and proteins can adsorb. This problem is particularly evident for proteins. These analytes are amphiphilic, such that their structure and chemical environment determines their characteristics (e.g. charge, polarity, and hydrophobicity).

The interactions of proteins at the liquid–solid boundary of fused-silica CE capillaries have been thoroughly investigated. Forces that are invoked during these interactions include electrostatic, ion pairing, hydrophobic, and the formation of hydrogen bonds. In CE separations adsorption equilibria between proteins and the capillary wall cause severe zone broadening. Peaks also become asymmetric, which leads to decreased analyte resolution and separation efficiency. Furthermore, a changing capillary surface also affects the magnitude of the EOF, and analyte separations become irreproducible.

To negate analyte–wall interactions, major efforts have been directed toward shielding or inverting the negative charge on the capillary wall. Various capillary coatings have been described [for a review of this subject, see Schomburg]. These include polymers, such as polyacrylamide (PAA), polyethylene glycol (PEG), polyethylenimine (PEI), PVA, aminopropyltrimethoxysilane (APS), and C8 and C18 phases that contain siloxane-bound anchor groups for covalent attachment to the capillary surface. Alternatively, static coatings such as PEI and polybrene have been adsorbed on the capillary surface prior to the analysis of peptides or proteins. Similarly, dynamic coatings such as PVA can be added to the BGE in an attempt to eliminate the interaction of analytes with the capillary wall. There have also been some investigations of the use of polymeric capillaries. However, these were difficult to make with a consistent small ID, and did not readily overcome the issue of protein interaction with the capillary wall, since even polymers can take on a charge during electrophoresis.
By design, all capillary coatings change the chemistry of the silica surface. Characteristics of the polymer or chemical coating determine the nature of the capillary surface. For example, hydrophilic neutral coatings (such as PVA, PEG, and PAA) impart no charge to the capillary wall and effectively eliminate EOF. In these capillaries, analyte resolution is based solely upon the differences of electrophoretic mobility of each analyte. Other coatings such as PEI, APS, polybrene, or surfactants such as cetrimidinium bromide reverse the charge on the capillary wall, and EOF flows from the cathode to the anode. CE capillaries coated with such positively charged materials have been shown to be especially advantageous for the analysis of basic proteins. More recently, we have reported that a polybrene-coated capillary is very useful for the analysis of the protein composition of physiologically derived fluids (such as aqueous humor). Indeed, separations in a polybrene-coated capillary were found to be less affected by the salinity of this fluid than other tested capillary coatings. In fact, in capillaries that were coated with a neutral polymer, we found that the high salt concentration of these samples prevented the separation of the proteins that were present in physiologically derived fluids. Often only one peak was observed during separations under these conditions.

For CE/MS experiments, the use of a coated capillary further complicates this methodology. If the coating is not sufficiently anchored to the capillary wall, it can bleed into the mass spectrometer. Here it may ionize, thereby generating a large chemical background or interfering with electrospray processes to impair stability or reduce analyte sensitivity. Hence, in addition to preventing analyte adsorption, the coating has to be stable and remain in the capillary. Most of those described above, with the exception of the dynamic coating strategy, have been successfully used for protein analysis by CE/MS. In general, coatings that invert the charge on the capillary wall have been preferred for the CE/MS analysis of proteins. This can be attributed to the stability of such coating in acidic BGEs, which is a regime that also promotes the formation of positively charged analytes, thereby enabling the use of positive ion MS conditions.

### 3.4 Capillary Electrophoresis/Mass Spectrometry Compatible Buffers

As alluded to above, the BGE used in the CE capillary to separate analytes can be detrimental to electrospray MS performance. Buffers of relatively high ionic strength are often used for CE separations, since these help to prevent analyte–analyte and analyte–wall interactions. Involatile salts are also a favorite choice for CE separations in conjunction with detection methods other than MS. By contrast, volatile buffers (e.g. ammonium salts) of low concentration, ionic strength, and conductivity are typically used for most CE/MS experiments. This is to ensure stable electrospray conditions and help prevent contamination of the mass spectrometer by salts and ultimately instrument break down. For peptides and proteins, Moseley et al. found that acidic buffers of low ionic strength provided the best CE/MS sensitivity when using a sheath liquid interface. More recently, Wahl and Smith compared the effect of BGE composition on CE/MS using both sheath liquid and sheathless electrospray interfaces. The results of this study were in good agreement with theory, and showed that CE/MS sensitivity was reduced with increasing buffer concentration and ionic strength. In addition, comparison of ammonium acetate–acetic acid and sodium phosphate buffer systems indicated that at a 1 mM concentration the latter buffer provided a seven-fold less signal-to-background ratio than the volatile acetate system. This was attributed to the difference in ionic strength and volatility of the examined BGEs. Other results of these studies demonstrated that the sheathless interface often provided better analyte detectability than a sheath liquid interface for most buffer systems. Likewise, a smaller bore capillary allowed improved tolerance of the buffer system, and this was attributed to the lower BGE flow rate. The BGE flow rate in a 10 µm ID CE capillary is approximately 0.8 nL min⁻¹ for a 10 mM ammonium acetate–acetic acid BGE.

In other studies, organic modifiers have been added to the BGE, to aid analyte solubility. The use of organic modifiers also changes the physical properties of the separation solution, which can change the magnitude of the EOF. The organic solvent can alter the thickness of the electrical double-layer at the capillary wall, and/or change the viscosity of the BGE. As demonstrated in Figure 8, a nonaqueous BGE can also offer advantages for CE/MS analyses of hydrophobic peptides. Here, an ammonium acetate–formic acid BGE system dissolved in a mixture containing only acetonitrile and methanol (75:25 v/v) was used to separate two hydrophobic peptides, namely gramicidin S and bacitracin. Both of these analytes are only sparingly soluble in aqueous solution, and poor analyte sensitivity was demonstrated using a conventional aqueous CE/MS BGE (data not shown). However, a nonaqueous BGE permitted efficient analysis of these analytes by CE/MS, when using a sheath liquid interface (consisting of 5 mM ammonium acetate in 80:20 v/v 2-propanol–water). Indeed, we were able to detect a number of minor contaminants in the samples of both peptides by CE/MS using the nonaqueous BGE system (see Figure 8).
In addition, more recently, nanoelectrospray MS has been used to analyze peptide and protein fractions that were collected following analyte separation by CE.\(^{(152)}\) In this area of research, one of the more attractive off-line couplings of CE with MS has been described by Zhang and Caprioli\(^{(149)}\). They built a moving target system on which components eluting from the CE capillary were deposited. Specifically, the eluent of the CE capillary was collected onto a cellulose membrane that was fixed on the MALDI/TOFMS instrument target, and preloaded with matrix-assisted laser desorption/ionization (MALDI) matrix (e.g. \(\alpha\)-cyano-4-hydroxycinnamic acid). The process of depositing small amounts of aqueous solution on the membrane caused the matrix to partially dissolve, which in turn stimulated cocryrstallization of analytes and matrix in preparation for subsequent MALDI/TOFMS analysis of the separated analytes. The target was mounted on the mobile block of a syringe pump to allow a single sample track across the membrane, with a time window of \(\sim3.3\) min. Detection limits (DLs) \((S/N > 3)\) were found to be \(\sim50\) amol for neurotensin and \(\sim250\) amol for cytochrome \(c\) and apomyoglobin. Such DLs are likely to be attributable to the fact that these analytes were not subjected to further manipulation following their collection from the CE capillary. Clearly, this ingenious method overcame some of the early challenges that were experienced as CE was coupled on-line with MS. However, other methods for the off-line coupling of CE with MS, that advocate manipulation of collected analyte solutions may be less favorable. As mentioned above, manipulation of dilute solutions of peptides and proteins can lead to significant losses. Therefore, in our opinion, many of the reported off-line strategies for coupling CE with MS are less attractive techniques for the analysis of peptides and proteins than on-line CE/MS.

The coupling of CE on-line with MS has been the subject of many reports and several reviews. Therefore, the following is a brief discussion of this area [see elsewhere\(^{(5,109,153–158)}\) for more comprehensive review of this subject matter].

### 4.2 Sheath Liquid Interface

The sheath liquid interface has become one of the most preferred methods for connecting the CE capillary to the mass spectrometer. Briefly, the CE capillary is extended though the ion source, and is surrounded by a coaxially delivered sheath liquid.\(^{(7,8)}\) This approach has been used for both electrospray and continuous-flow fast atom bombardment (CFFAB) interfaces.\(^{(155)}\) Conceptually the sheath liquid interface is the same for both MS devices with the coaxially delivered solution providing sufficient solvent flow through the interface. The sheath liquid also ensures electrical connectivity across the CE capillary,
and in the ESI interface provides the electrical contact for the ESI voltage.

Some challenges have been reported for both ESI and CFFAB interfaces. For the CFFAB design, the ID of the CE capillary must be small (typically <13 µm ID). This interface is inserted into the high vacuum of the mass spectrometer, and vacuum-induced flow becomes a problem for wider bore capillaries, resulting in a dramatic loss of separation efficiency. The ESI interface does not suffer this problem since ionization occurs at atmospheric pressure, and capillaries as large as 100 µm ID have been successfully coupled to this interface. However, as mentioned above, use of such wide-bore capillaries establishes further constraints on buffer concentration and ionic strength, which can impair both analyte resolution and CE separation efficiency.

Karger et al. investigated ionic mobility in CE/MS using a sheath liquid interface. Since ions migrate towards both anode and cathode, ionic components of the sheath liquid can migrate into the separation capillary. Both sharp and diffuse ionic boundaries were detected, and resulted in migration delays, inversion of migration order, and often loss of analyte resolution. This effect is shown in Figure 9(a) and (b). Here, while the BGE was the same in the two experiments, replacement of a sheath liquid containing 1% acetic acid in 50% methanol–water by 20 mM TFA in 50% methanol–water had a dramatic effect on the analysis of a mixture of proteins. The time of the separation was compressed and the protein resolution was significantly different. Hence the sheath liquid is a further parameter that requires close attention. In addition to avoiding the possible detrimental effects on analyte separation (described above), careful selection of the sheath liquid can also lead to the use of BGEs that contain involatile buffers. Ions present in the sheath liquid can penetrate the CE capillary to prevent such involatile salts from entering the interface. Furthermore, this process can effectively remove adducts (e.g. phosphates) from proteins prior to entering the mass spectrometer. Similarly, we have noted on occasion that proteins may not be detected at the mass spectrometer (even though they have been seen to migrate passed a UV window that is close to the inlet of the CE capillary) when using a mostly organic sheath liquid interface. In addition to the above explanation, we have postulated that the mostly organic sheath liquid causes the proteins to precipitate as they elute from the CE capillary. As a result, proteins are neither ionized nor detected.

One of the major disadvantages of the sheath liquid interface is that it can introduce a large chemical background into the mass spectrometer. This tends to compromise analyte sensitivity, which is a problem that has been addressed by the use of a sheathless interface, or low sheath flow design. Kirby et al. advocated this latter approach. Reduction of the annular volume between the sheath liquid needle and the CE capillary allows the use of lower sheath liquid flow rates (<100 nL min⁻¹ has been reported). As a result, less chemical noise is detected and the S/Ns of analytes of interest are improved. A particularly useful application of this interface is its use in conjunction with CE capillaries that have negligible or zero EOF. Such capillaries require the makeup flow of the sheath liquid to maintain stable spray conditions.

Figure 9 CE/MS analysis of a model mixture of proteins: 1, cytochrome c; 2, lysozyme; 3, aprotinin; 4, myoglobin; 5, RNase A; 6, β-lactoglobulin B; 7 and 8, β-lactoglobulin A and carbonic anhydrase; 9, α-chymotrypsinogen A. CE/MS conditions were BGE 20 mM β-alanine–formic acid at pH 3.4, CE capillary was 75 µm ID by 60 cm. Separation voltage was 25kV. Liquid sheath interface was (a) 1% acetic acid in 50% methanol–water and (b) 20 mM TFA in 50% methanol–water. (Reprinted with permission from F. Foret, T.J. Thompson, P. Vouros, B.L. Karger, Anal. Chem., 66, 4450–4458 (1994). Copyright 1994, American Chemical Society.)
Most recent reports of the connection of CE with MS have focused upon the use of an ESI interface. This is due primarily to the fact that the outlet of the CE capillary is at atmosphere, hence the MS vacuum does not influence analyte separations. In addition, a major limitation of the CFFAB source is that the ions produced typically exhibit a small number of charges. For proteins, this requires an instrument with an extended mass range. By contrast, the ESI produces multiply charged gaseous ions from solution. Since all mass spectrometers measure mass-to-charge ratio (m/z) values, this effectively extends the mass range of the instrument and permits the analysis of large proteins using relatively inexpensive mass analyzers (such as standard mass range quadrupole instruments).

### 4.3 Liquid Junction Interface

The liquid junction interface has also been used to couple CE on-line with both ESI and CFFAB interfaces. In this device the CE capillary is placed in a buffer reservoir. Analytes are transported to the mass spectrometer using a transfer line that is positioned in the buffer reservoir in close proximity (∼10–25 µm) to the CE capillary. Alignment of these capillaries has been shown to be critical, and Henion et al. have described a modified liquid junction interface in which the CE and transfer capillaries are self-aligning. One of the advantages of the liquid junction interface is its tolerance of involatile BGEs. In addition, this interface was used to successfully couple gel-filled CE capillaries to the mass spectrometer. However, the ease of set-up and use of the sheath liquid interface have ensured that this interface is usually the one of choice, especially by those new to CE/MS.

### 4.4 Sheathless Interfaces

A sheathless ESI interface has several significant advantages over sheath and liquid junction designs. First, there is a reduced chemical background. Also, since there is no makeup solution that can compete with analyte for the available charge, sensitivity is enhanced. For peptides and proteins, low femtomole sensitivity has been reported. In addition, more recently, peptide sequencing with attomole sensitivity has been reported for a combination of mPC/CE with a sheathless ESI interface, using an ion trap mass spectrometer (see Figure 6).

Sheathless ESI interfaces typically conform to one of six major designs, shown in Figure 10(a–f). The

![Figure 10](image_url)
simplest sheathless interface (Figure 10a) is usually made by etching and tapering the fused-silica, which is then coated with gold\(^{161}\) or conducting epoxy.\(^{109}\) Other designs include the insertion of a wire into the outlet of the CE capillary (Figure 10b)\(^{82}\) or the use of a thin wire between the CE capillary outlet and a transfer capillary (Figure 10c).\(^{111,128}\) A low-volume metal union has also been used to connect a transfer line to the CE capillary (Figure 10d).\(^{82}\) Smith et al. described the use of a dialysis tube to cover a fracture close to the outlet of the capillary (Figure 10e),\(^{162}\) and more recently, Hunt et al. described a further sheathless CE/MS interface (Figure 10f).\(^{96}\) Each of these designs has its merits and challenges, and these have been evaluated (for some of the above-mentioned interfaces) by Herring and Qin.\(^{82}\) They evaluated the most appropriate CE/MS methodology for the analysis of phosphorylated tryptic peptides of myosin I heavy chain (MIHCK). Again, a method of analyte preconcentration on-line with the CE capillary was preferred to allow efficient sample handling. The findings of Qin and Herring are summarized in Table 1. One of the most common problems encountered during these studies was electrolysis and the generation of hydrogen bubbles at the junction of the CE capillary and the ESI emitter.\(^{82}\) This invariably stopped the EOF, thereby terminating the experiment. To overcome this significant challenge, Qin and Herring inserted a 10-µm palladium wire into the outlet of the CE capillary (Figure 10b), which also acted as the ESI emitter. In their hands, this interface was reported to be easy to construct. In addition, a very useful property of palladium for this application is that it can absorb >900 times more hydrogen than its own volume. Therefore, unlike some of the other interfaces tested in their study, this simple sheathless CE/MS interface design did not suffer problems associated with hydrogen bubbles halting EOF. However, this interface did tend to induce the oxidation of some peptides.\(^{82}\) For example, multiple oxidation of bombesin (EQRLGNQWAVGHLM) was demonstrated (see Figure 11). The placement of the palladium wire within the CE capillary also caused turbulence, and some loss of analyte resolution. However, these investigators were able to obtain good MS sensitivity for the two phosphopeptides expected in a tryptic digest of MIHCK, using this interface in conjunction with their adaptation of on-line solid-phase extraction/capillary electrophoresis/mass spectrometry (SPE/CE/MS).\(^{82}\)

that a consensus will be reached by the community as to the most appropriate way to achieve a sensitive and robust design for this approach of interfacing CE with MS.

4.5 Sample Preparation

As mentioned above, extreme caution is required during preparation of dilute solutions of peptides and proteins. These analytes readily adhere to every surface that they contact. Therefore, manipulations need to be minimized. However, biologically relevant peptides and proteins are often most soluble in solutions of high ionic strength. Such solutions are usually not optimal for separation by CE. Typically, these solutions will reduce the effect of stacking mechanisms, or compress the pH gradient in cIEF separations.\(^{(15,116)}\) Clearly, the salt concentrations need to be reduced. However, this should not be at the expense of analyte concentration. In this regard, use of an on-line sample preparation (e.g. SPE/CE/MS or mPC/CE/MS) appears to be most appropriate.\(^{(27,50–96)}\)

As described above, these techniques enable analyte preconcentration and sample cleanup with minimal intervention by the operator. Improved analyte recovery results. Furthermore, as we have found in our studies, the salt in the sample matrix may aid protein recovery from the solid phase or impregnated membrane.\(^{(129,130)}\) Also, traces of salt that remain after such on-line cleanup may improve analyte stacking, provided a positively charged capillary is used for analyte separation.\(^{(129,130)}\) For peptides the combination of reversed phase HPLC offline with mPC/CE/MS has been proven to be a sensitive method of analysis, since subsequent sample preparation involves merely removing the organic solvent from fractions and diluting the residue in a suitable aqueous solvent.\(^{(57,88,96)}\) This method could be further improved by on-line coupling of these techniques, as has been demonstrated by Jorgenson’s group.\(^{(163)}\) However, this tandem technique requires that the mass spectrometer is capable of high sensitivity at fast scan rates, since the CE separation is usually complete in just a few seconds. As such the development of instruments for fast scanning, highly sensitive electrospray ionization/time-of-flight mass spectrometry (ESI/TOFMS) will make this technology more viable.\(^{(120)}\)

An area that has currently received only scant attention is that of on-line digestion CE/MS.\(^{(164)}\) Such methodology, demonstrated by Kuhr and his group, appears to be a useful way of generating peptide maps of small amounts of biologically relevant proteins.\(^{(58,57,164)}\) In conjunction with on-line SPE/CE/MS or mPC/CE/MS, digestion in an open-tubular enzyme capillary or an enzyme-modified solid support would appear to be a powerful methodology for proteomic research. Furthermore, up-front separation by an appropriate chromatographic step (either HPLC or CE) could provide an attractive method for characterizing the protein composition of a biological system, that once optimized would need little operator intervention. Hence analyte losses and sample contamination should be minimized. On-line, automated peptide/protein sequencing using tandem mass spectrometry (MS/MS) could also be achieved by this integrated approach.

5 METHOD DEVELOPMENT

Capillary preparation is the first consideration during the development of a new method. The approach taken is dependent upon the separation mechanism that is considered to be appropriate to yield analyte resolution. The simplest approach is to use a solution of sodium or potassium hydroxide (or methoxide) to etch and clean the silica surface. Following such cleaning, the capillary is usually washed with water and BGE. The capillary is then considered to be ready for analyte separation. However, for peptide analysis it is our experience that the capillary needs to be conditioned before it yields optimal performance. Therefore, in our hands, we usually analyze a standard solution of peptides until reproducible performance is obtained.\(^{(165)}\) Typically, 2–5 analyses of the standard peptide solution are sufficient to condition the capillary, but, as noted above, there are some capillaries that do not yield acceptable performance. During our early encounters with CE and CE/MS, we would replace such capillaries and restart the laborious, time-consuming conditioning procedure. As we became more sophisticated users of CE, we found that flushing those capillaries that would not condition (in the conventional manner described above) with a solution of 70% formic acid in 1-propanol would restore CE separation performance.\(^{(166)}\) This solution has been reported to remove hydrophobic proteins from HPLC columns, and may be flushing hydrophobic contaminants (that were introduced during manufacture) from the capillary. However, it was also apparent that the silica surface was modified, since subsequent washing of the CE capillary with potassium hydroxide immediately degraded the CE performance. In addition, we proved that this effect was not merely due to the use of a concentrated acid solution, since rinsing the capillary with 1 M hydrochloric acid was not able to restore the separation performance.\(^{(166)}\)

It has been shown that in free solution peptide migration follows a linear relationship with \(m^2/\lambda z\), where \(m\) is the molecular weight of the peptide and \(z\) is its
charge or valency [see McCormick \cite{167} for a review of this subject]. Consequently, several computer programs have been developed to correlate the pI of a peptide with the charge on the molecule at a given pH. Therefore, if the peptide composition of a mixture is known, the free solution CE conditions that would effect separation can be predicted. From these considerations, the most important parameter that effects the selectivity of the separation is the pH of the BGE. Other parameters such as the ionic strength of the BGE, capillary dimensions, temperature, and electrical field strength influence analyte separation in free solution. However, for peptides, the most direct route to method optimization is to change the pH of the BGE. As mentioned above, BGEs prepared with volatile salts have been reported to be most suitable for all CE/MS studies. Acidic BGEs are usually prepared with mixtures of ammonium acetate and acetic acid solutions, and those at higher pH are typically composed of mixtures of ammonium acetate and ammonia solutions. One issue with these solutions is that they do not exhibit high buffer capacity, and this can lead to irreproducible analyte migration times, as ions are depleted from the BGE. Frequent replenishment of the BGE with fresh solution can overcome this limitation and lead to improved reproducibility of analyte separation and migration.\cite{165}

In our studies, we have found for small peptides (molecular weight < 1500) that a solution of 2 mM ammonium acetate in 1% aqueous acetic acid provides a reasonable BGE for analysis by CE/MS.\cite{86–88}

In addition, increasing the acetic acid concentration to 5% tends to enhance peptide separation.\cite{128} Since the pH of the 5% acetic acid solution is very close to that of the 2 mM ammonium acetate in 1% aqueous acetic acid BGE, we attribute the increased peptide resolution to an increased BGE viscosity.\cite{128} More recently, while such ammonium acetate BGEs can be used effectively in uncoated fused-silica capillaries, we have tended to favor the use of the polybrene coating for CE/MS analysis of peptides.\cite{128} As mentioned above, this coating reverses the charge on the capillary wall and tends to prevent peptide adsorption. However, it is our experience that this coating requires conditioning, with the reproducibility of peptide migration times and resolution improving with each analysis. Typically, a polybrene-coated capillary is conditioned within five analyses. This capillary then yields optimal performance for 15–20 separations, after which it has to be completely stripped and recoated (a cycle that can be repeated about 20 times before replacing the capillary).\cite{128} Adding polybrene to the BGE to coat the capillary dynamically during use would keep it functional longer. However, this is not an option for CE/MS studies, since this reagent would enter the mass spectrometer and interfere with ESI processes and method sensitivity. As noted above, the issue of limited CE and CE/MS concentration sensitivity has been addressed by several groups through the development of analyte concentrators and membrane preconcentrators. These have proved to be extremely useful for the analysis of low concentrations of biologically active peptides and enzymatic protein digests. Indeed, we now use mPC/CE/MS exclusively for this application, since it minimizes sample handling, which maximizes analyte recoveries.

The development of conditions for the separation of proteins is considerably more complex than the optimization of CE parameters for peptide resolution. Protein denaturation, aggregation, and precipitation and adsorption on the capillary wall are all factors that can degrade CE performance.\cite{129,130} For most protein separations, a coated capillary is usually essential. Thereby, the complexity of analysis is already increased. In addition, there are a number of separation mechanisms (including free solution, cIEF, cITP, molecular weight sieving, etc.) that can be used to effect the separation of the analytes.\cite{11–24} All of these options and the usual CE parameters need to be considered prior to attempting to separate proteins by CE. We recently evaluated a number of coated capillaries for the analysis of aqueous humor.\cite{168} As noted above, we found that the salt matrix of this physiologically derived fluid interfered with the separation of the proteins that are present in this fluid. In most cases, only a single peak was detected.\cite{168} However, use of a polybrene capillary permitted good resolution of the components of this important physiological fluid. We have also found that a BGE composed of ammonium acetate and acetic acid is very suitable for protein analysis by CE/MS, with increasing acetic acid concentration often improving analyte resolution.\cite{168} Again, we are strong advocates of the use of mPC/CE/MS for this application, since this technique enables both analyte concentration and sample cleanup without excessive sample handling (see Figure 7).\cite{129,130}

# 6 SEQUENCING PEPTIDES BY CAPILLARY ELECTROPHORESIS/TANDEM MASS SPECTROMETRY

Peptide sequencing by MS/MS, with two mass analyzers coupled via a collision cell, was pioneered by Hunt et al.\cite{169} It is a technique that has provided the sequence of peptides at concentrations that are below the typical DLs of conventional Edman chemistries. The development of the ESI interface, along with on-line condensed-phase chromatography [high-performance liquid chromatography/mass spectrometry (HPLC/MS) and CE/MS] has further extended the use of this approach for peptide sequencing. DLs are often in the sub-picomole range of material. Typical peptide cleavages are shown
in Figure 12. Random cleavage of the amide bonds is desired, and often results from low-energy collisions (as are typical in triple-quadrupole, hybrid, or ion trap instruments). It is often possible to read the peptide sequence from both the N- and C-termini from these data. However, there is ambiguity since isobaric amino acids (e.g. leucine and isoleucine) give rise to the generation of identical fragment ions. On occasion, these may be resolved by high-energy collisions, which induce side-chain fragmentation. More recently, the use of protein database searching algorithms has also tended to overcome the problem of identifying the isobaric amino acids. By this approach, peptide sequences are derived by matching the acquired data with peptides that are produced from the known proteins in the database, hence there is often little ambiguity in the amino acid sequence.

In recent years, with the exception of a few isolated cases, high-performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS) has dominated this area of research. This can be attributed, at least in part, to a better concentration sensitivity of HPLC as compared with CE. Furthermore, chromatographic peak widths may be greater in HPLC separations and more compatible with scan rates of the scanning mass spectrometer. In addition, coupling of the HPLC column to the electrospray interface has been much less challenging to achieve than interfacing CE to the same ionization source. However, CE does afford a second complementary dimension of separation, and we have exploited this to sequence MHC class I peptides. In a first dimension, these immunologically important peptides are isolated by reversed-phase HPLC. Each fraction is then concentrated to remove the acetonitrile, and analyzed by mPC/CE/MS. Indeed, the development of SPE/CE/MS and mPC/CE/MS has provided technology that has a comparable concentration sensitivity to that of HPLC. However, analyte peak widths of SPE/CE/MS and mPC/CE/MS separations are a challenge to the scanning mass spectrometer (e.g. triple-quadrupole or sector-quadrupole hybrid instrument). As mentioned above, MS sensitivity is reduced at high scan rates. Slowing the rate of data acquisition is often not an option, particularly for CE separations. Often, mass resolution is sacrificed in both mass spectrometers MS1 and MS2 to attempt to regain some of the sensitivity that is lost to the fast scan. Such a compromise usually leads to a more difficult spectrum interpretation, since isobaric peptides may be introduced simultaneously into the collision cell. Fragments of both are then detected in the resultant spectrum. A further compromise of this approach is that mass accuracy may be sacrificed, with an error in the m/z measurement of fragment ions no better than ±1 Da. Since this is the mass difference between some amino acids (e.g. I/L and N) ambiguity is introduced into the peptide sequence. However, this situation is often independent of the mode of separation, when sensitivity is pushed to the limits of the scanning mass spectrometer. Reported peptide sequencing sensitivities using scanning MS are comparable to those for HPLC/MS/MS (5 fmol on-column) and mPC/CE/MS (10–50 fmol on-column). More recently, ion trap devices (ITMS) and FTMS instruments have been used to acquire peptide sequence data. Indeed, as described above, Hunt et al. have reported 50 amol sensitivity for sequencing MHC class I peptides by mPC/tITP/CE/MS with an ion trap instrument (see Figure 6). Such increase in sensitivity can be attributed to the manner in which these instruments are operated. In these devices ions are trapped and accumulated for a specific length of time. Furthermore, in MS/MS experiments all but the ions of interest are ejected from the trap prior to...
peptide fragmentation and subsequent analysis of the generated fragment ions. This approach often leads to a less complex tandem mass spectrum, and if the trap is not overloaded with ions, mass accuracy can be better than is achieved by a scanning instrument. In many areas of research such an increase in sensitivity can reduce the need for growing huge cell colonies, which is both costly and time-consuming. In studies of MHC class I peptide cell colonies, in excess of $10^{10}$ cells are extracted in contemporary methodologies to yield sufficient peptide for sequencing.\(^{96,170,171}\) As MS sensitivity is improved this number should fall significantly, and sequencing peptides from a colony of $10^6$ cells may become routine in the very near future.

### 7 Future Directions

Developing practices in the area of proteomics will inevitably be more demanding on the sensitivity of analytical methods.\(^ {11}\) Current practices demand that the sensitivity of protein sequencing methods is comparable to that of slab gel silver staining techniques.\(^ {110}\) While these approaches are yielding results, it is likely that many biologically significant proteins will not be detected or characterized. However, at the sensitivity levels that will be required in this area of research, sample manipulations become a major challenge. Both analyte losses and sample contamination by ubiquitous human proteins (such as keratin) become significant issues at picomolar concentrations.\(^ {110}\) Automated preparation and analysis of low-volume, low-concentration samples of high complexity will be required to overcome these issues. Clean-room technology is also likely to become a major requirement of these investigations. Figeys et al. have proposed a solution to these issues.\(^ {110}\) These investigators have suggested the use of coupled microfabricated, integrated analytical modules with MS for this application, and they have proposed microfabricated device/mass spectrometry (MFD/MS) as the acronym for this technology.\(^ {110}\) While research on these devices is in its infancy, such a miniaturized approach coupled with a sensitive mass spectrometer could provide the DLs required in the next generation of proteomic studies. Furthermore, with careful design of the array, on-chip protein isolation, digestion, and analysis could be accommodated in this nanoevironment.\(^ {110}\) However, the use of nanotechnologies will provide new challenges. First, creative coupling of the macro world of biochemistry to the nanoanalytical environment will be required. In this regard, the lessons learned from the development of mPC/CE/MS and SPE/CE/MS technologies should aid these studies, particularly in the area of reducing potentially long sample injection times, caused by slow liquid flow rates in these nanodevices. The sensitivity of protein sequencing will also require further creative input. In this area, interfacing the microfabricated array to the mass spectrometer will need particular attention.

So far, since MFD/MS research is in its infancy, there have been few reports in the scientific literature.\(^ {110,114,115,173}\) Most devices are prepared using technology that was first described in the computer microchip industry. Typically, reservoirs and microchannels are etched into glass, which is bonded to a second piece of glass, and electrodes are inserted to complete the device. There have also been limited reports of the use of polymers to prepare for this application, and this is an area that may require much more attention. It is known from conventional CE that proteins absorb to glass capillaries, leading to the development of a large number of capillary coatings to prevent protein adsorption to the capillary wall (see earlier discussions).\(^ {110}\) It is envisaged that similar coatings will need to be applied to a microfabricated device (MFD) to prevent protein adsorption on these devices, and improve separation or manipulation of these important analytes in the nanoevironment.

Currently, there is no consensus in the literature as to the most appropriate method for interfacing an MFD with a mass spectrometer. It is agreed that the micro- or nanoelectrospray interface is the most efficient ionization source for this application.\(^ {110,114,115,173}\) In one of the approaches described, an array of nine channels was continued to the edge of the device, which served as the ESI/mass spectrometer interface.\(^ {173}\) Analytes were mobilized by the application of pressure to the appropriate reservoir and ionized directly from the edge of the unit. The different channels were moved sequentially in front of the inlet orifice of the mass spectrometer to permit the characterization of individual analytes. Ramsey and Ramsey have described a similar approach, and demonstrated an MFD/MS separation with their device.\(^ {114}\) In contrast, Figeys et al. preferred to use a transfer capillary and a liquid junction microspray (see Figure 10c) to interface an MFD to the mass spectrometer.\(^ {110}\) Enhanced MS sensitivity was given as the reason for their preference for this interface. However, it does significantly extend analysis times. This technique may be most suitable for enhancing separations, by a combined microfabricated device/capillary electrophoresis/mass spectrometry (MFD/CE/MS) approach. More recently, Foret and Karger described the use of ionspray directly from the edge of the MFD.\(^ {174}\) This device includes the ability to apply a nebulizing gas to aid the electrospray processes. However, the use of the nebulizing gas induces hydrodynamic flow within the device, hence a makeup solvent is
required. The use of a makeup solvent inevitably dilutes the separated analytes prior to their transport into the mass spectrometer, and may reduce the ultimate sensitivity of this approach. However, careful selection of this solvent may aid ionization efficiency and thus tend to improve method sensitivity.\footnote{174}

A further technology that is expected to improve MS sensitivity is the development of the highly sensitive ESI/TOFMS,\footnote{120} and electrospray ionization quadrupole time-of-flight mass spectrometry (ESI/QTOFMS) and a quadrupole ion trap coupled with a reflecting TOF instrument.\footnote{175,176} The development of such instruments is well under way. In addition to high sensitivity, these instruments have a short duty cycle, which allows very fast data acquisition, with no loss of sensitivity. These instruments also provide a constant medium resolution (>5000 full width at half-maximum definition) and good mass accuracy. The use of isotopic labeling (as is achieved when enzymatic protein digests are carried out in \(^{18}\)O-labeled water) can aid peptide identification with MS/MS data since only Y ions will contain this label. The mass resolution of the TOF instruments allows \(^{18}\)O-enriched ions to be readily identified in MS/MS spectra, to facilitate peptide sequence identification.\footnote{177}

In summary, it is clear that there will need to be a significant pursuit of more sensitivity for CE/MS. In this regard, MFD/MS may, with further development and possible coupling to a highly sensitive mass spectrometer (such as ESI/TOFMS), provide the technology that is needed for future generations of proteomic research. However, lessons learnt in the macro world of CE/MS will need to be heeded as new MFD and MS interfacing techniques are developed. In particular, input by materials scientists may provide improved surfaces to prevent interaction and loss of peptides and proteins within the channels of MFDs. Assuming that these challenges will be overcome, technology for the isolation, manipulation, digestion, and sequencing of extremely low levels of biologically active proteins will become a reality within the next few years.

**ACKNOWLEDGMENTS**

The authors thank Mrs Diana Ayerhart for her help in preparing this article. They are also grateful to Christopher Herring and Dr Jun Qin (Laboratory of Biophysical Chemistry, National Heart, Lung, and Blood Institute) for sharing the results of their studies of microspray CE/MS interfaces and Professor Hunt (University of Virginia) and Professor Karger (Barnet Institute North-eastern University) for graciously sharing their work. The support of funding by Mayo Foundation, Finnigan MAT, Beckman Instruments, AHAF, and NIH is gratefully acknowledged.

1 Introduction

Owing to their lipophilic character, the solubilization and separation of membrane proteins and lipoproteins normally require the use of detergents. Consequently, classical protein purification strategies, designed for water-soluble proteins, are of limited value and the number of reports dealing with the separation and characterization of such proteins is limited. Moreover, their hydrophobic nature induces self-association into noncovalent multimers, and therefore all separative methods require a prior procedure such as tedious sequential gradient ultracentrifugation for sample preparation, with the risk of affecting the results. Although the available methods for the final separation of these hydrophobic proteins are numerous, theirs high hydrophobicity and the presence of detergent makes most of these available methods expensive and technically demanding. The traditional approaches by SDS/PAGE are not only cumbersome but also rather ineffective for evaluating differences in small molecular masses and the run times required are very long, typically more than 20–30 h. CE is emerging as a powerful separation technique for lipoproteins but the number of reports on membrane proteins is still limited. It is not surprising that HPLC techniques, given their wide versatility, relative ease of use, and high resolution, may be considered the most valuable tool for the characterization of virtually any hydrophobic protein. Moreover, HPLC is not a destructive technique and therefore proteins, once separated, are available for other analytical investigations, such as by SDS/PAGE. In any case, before loading a sample on any HPLC system, a preseparation of membrane proteins or lipoproteins, according to their hydrophobic characteristics, must be achieved by selective extractions. The pretreatment of these proteins facilitates subsequent separation and provides a first guideline for the choice of detergent. It is a general rule, in fact, that when choosing the detergent for the running buffers, one should use the one with which the protein was solubilized, if possible. It is also advisable to use less denaturing detergents and nonionic detergents for solubilization and likewise as an additive to the running buffers, in order to retain the biological activity of proteins. The presence of detergent in all steps preserves the subsequent tendency toward association and aggregation and the possibility of nonspecific interactions with the support used for chromatographic separation.

Although lipoproteins and membrane proteins show common features, specific protocols for the separation of each group of proteins have recently been proposed, and therefore they will be presented separately.

2 CHROMATOGRAPHY OF MEMBRANE PROTEINS

Methods for the separation and characterization of membrane proteins differ depending on the type of interaction
of the protein with the membrane: proteins embedded in a lipid bilayer or associated with membrane structures. In the latter case, usually ionic interactions or hydrogen bonds are involved in the anchorage, and therefore the protein may be removed by gentle solubilization with buffered salt solution and then analyzed. Dilute sodium hydroxide and sodium hydrogen carbonate (between pH 10 and 12), concentrated salt solutions, and complex-forming substances such as ethylenediaminetetraacetic acid (EDTA) and ethylene glycol bis(β-aminoethyl ether)-N,N,N′,N′-tetraacetic acid (EGTA) are used satisfactorily for their solubilization. In the case of embedded proteins, they must first be extracted from the membrane structures and then isolated. Repeated freezing and thawing can be applied to dissolve the structures mechanically, thereby allowing most membrane-associated proteins to be removed. However, solubilization of the membrane is the most suitable approach. Chaotropic reagents such as urea and guanidine hydrochloride are now used less frequently, while solubilization using detergents is still in principle more practical. It is also advisable to use less denaturing detergents such as 3-[3-cholamidopropyl]dimethylammonio]-l-propanesulfonate (CHAPS), or nonionic detergents such as n-octyl β-D-glucopyranoside (OD) or n-dodecyl β-D-maltoside (β-DM) for solubilization.

Through the use of various reagents in different steps, the membrane proteins can be prepared according to their respective solubility and hydrophobic characteristics. The effort necessary for solubilization of the proteins increases with growing complexity of the membrane structure. In section 4.2.3 is reported a complete solubilization scheme for the thylakoid membrane of chloroplasts which contains the photosynthetic apparatus consisting of a large number of proteins, namely 40 different proteins assembled into two main complexes: photosystem I (PSI) and photosystem II (PSII). It will be shown that by selective extraction, a preseparation of membrane proteins according to their hydrophobic characteristics is achieved. This in turn allows further separation by use of different, mainly chromatographic and electrophoretic, methods.

Once the membrane proteins have been pretreated, several chromatographic methods may be used.

### 2.1 Methods for Protein Separation and Characterization

With regard to the membrane protein separation, strategies having general validity are reversed-phase high-performance liquid chromatography (RP-HPLC), affinity chromatography, size-exclusion high-performance liquid chromatography (SE-HPLC) or ion-exchange HPLC and high-performance membrane chromatography. Usually membrane proteins are organized as multimeric units, therefore no single technique is likely to be sufficient for the complete characterization of different proteins. It is important, therefore, to select a battery of complementary techniques that will ensure that the necessary separation is obtained. Specific considerations for selection of an appropriate battery of techniques are described in section 4.

Conventional gel permeation and ion-exchange chromatography on soft gel supports, although time-consuming, are used for the preparation of large quantities (10–50 mg) of pure proteins, while the preparation of smaller quantities is usually performed at low pressure [fast protein liquid chromatography (FPLC)]. HPLC, usually carried out at high pressure (300–400 psi), has been an essential tool for the quantitative and qualitative analysis of proteins. Its success increased when rigid supports, which are able to withstand high pressures and show chemical stability within the working range of biological separations, were introduced. The separation time decreased dramatically.

The first consideration in defining an HPLC method development strategy is to establish if we need proteins with the biological properties preserved or we simply need their characterization. Proteins vary widely in their physicochemical properties and these properties can have a great impact on the conditions necessary for HPLC analysis. Solution stability can differ widely from one protein to another, and for a given protein the solution stability can be highly dependent on pH, temperature, presence of denaturants or detergents, and other factors. Such factors must be explored as part of the separation development process in order to select appropriate conditions and an appropriate detergent under which artifactual denaturation is minimized. Other physicochemical properties to be considered include the presence or absence of free thiol groups or bound metals and the effect of the organic solvent used in RP-HPLC on the secondary or tertiary structure. Finally, the presence of detergent must be taken into account along with the possibility of nonspecific interactions with the support used for chromatographic separation. Furthermore, membrane proteins readily self-associate into noncovalent multimers. Hence in some instances one may wish to determine only covalent related substances and it is therefore appropriate to conduct the HPLC separation using conditions that dissociate the noncovalent multimers, whereas in other instances measurement of the extent of self-association may be an objective of the separation.

#### 2.1.1 Reversed-phase High-performance Liquid Chromatography

RP-HPLC offers the best resolution of all chromatographic methods, although up to now it has been rarely
used for the separation of membrane proteins. This is because under the separation conditions usually required in RPHPLC [elution with acetonitrile or 2-propanol gradient, in the presence of 0.1% (v/v) trifluoroacetic acid (TFA)], the membrane proteins can be recovered only partly and sometimes not at all. The advent of supports having reduced hydrophobicity, such as a C-4 column, has allowed the use of milder elution conditions with a consequent higher recovery of proteins (see section 4). Clearly, the application of organic solvents and acids causes the loss of the protein biological activity. Thus, RPHPLC is a powerful method for the isolation of membrane proteins, whose primary structure is to be investigated subsequently or whose identification is the main aim.

2.1.2 High-performance Affinity Chromatography

Analytical affinity provides a powerful means to purify proteins and other biomolecules with a basic two-step retention–chaotropic elution procedure with minimal nonspecific interactions and their subsequent elution in a highly purified state and in the native state. Successes of affinity chromatography for preparative purposes arose when researchers improved several key features of immobilized ligand interactions with eluting macromolecules, namely accessibility of immobilized ligand, selectivity of ligand interaction with soluble macromolecule, and reversibility of macromolecule binding, which allows their elution without denaturation. In this regard, important parameters for a successful affinity sorbent for bioseparations include mechanical, chemical and biological stability, and also the potential for nonspecific binding. Rigid matrices such as polymeric supports, silica and controlled-pore glass may suffer from nonspecific binding and low recovery. Cross-linked beaded agarose or cellulose offers a good compromise between mechanical stability and nonspecific binding. These matrices also have good chemical stability within the working range of biological separations and the product recovery is excellent. The interested reader is referred to other literature for a discussion of core chromatographic matrices themselves.\(^{1}\)

Once a matrix has been selected, the ligand is immobilized via a stable covalent bond to avoid progressive leakage and consequent capacity loss. The most common procedure to activate agarose is cyanogen bromide (CNBr), which results in the coupling of an amine group of the ligand or spacer through an isourea bond. Matrices prepared by this procedure can suffer from the serious drawback of high ligand leakage, while more stable linkages are produced by organic sulfonyl chlorides or epiphosphohydrins.\(^{2}\)

Lectin affinity chromatography is largely used for lipoproteins, while two steps with protein-specific ligands, namely immunoaffinity (IA) and transition-state ligands, are commonly used for the separation of receptors and enzyme proteins, respectively.\(^{3}\)

2.1.3 Size-exclusion High-performance Liquid Chromatography

The separation of membrane proteins may be achieved satisfactorily under non-denaturing conditions by SEHPLC. In this case, the size of the molecules or multimeric complexes is the basis of separation, although differences of 5–10 kDa in molecular weight are not sufficient for a significant separation. Since nonspecific interactions between the sample and support, and among different sample components, must be suppressed, sometimes the addition of denaturing agents, such as chaotropic reagents or sodium dodecyl sulfate (SDS), is required. Obviously, under these denaturing conditions, the resolution and yield are optimized in SEHPLC, along with good reproducibility of the results, but proteins may be denatured.

2.1.4 Ion-exchange High-performance Liquid Chromatography

Ion-exchange HPLC is based on the different ionic interactions between proteins and anionic or cationic charges of the support. Unfortunately, in this type of chromatography, protein interaction with the support is usually strong and the conditions used for elution are often denaturing. The advent of supports based on agarose, which owing to its hydrophilic characteristic has a lower level of nonspecific interactions with the sample, has renewed the use of ion-exchange HPLC for protein separations. However, in the particular case of membrane proteins, although the degree of resolution of ion-exchange HPLC is surpassed only by RPHPLC, interaction with the support is still too strong and other methods must be chosen, or detergents must be added to the separation buffers.

2.1.5 Hydrophobic Interaction High-performance Liquid Chromatography

Hydrophobic interaction HPLC can also be used for the isolation of membrane proteins, even if they are so strong that the sample can no longer be recovered from the column, even with the use of detergents or, in extreme cases, organic solvents.

2.1.6 High-performance Membrane Chromatography

Red cells, biomembrane vesicles, proteoliposomes, and liposomes noncovalently immobilized in gel particles or beads have been used as stationary phases
for biomembrane affinity analyses and ion-exchange chromatographic separations. Lipid monolayers coupled to silica beads have been utilized for membrane protein purification in detergent solution. Proteins are adsorbed on the liposome surfaces and subsequently separated by salt gradient elution on charged liposomes formed and entrapped in gel beads upon detergent depletion by dialysis. Hence both protein size and charge affect the separation and the elution time. These techniques, in the particular case of membrane proteins, have considerable potential because of their high resolution, short running times, and low nonspecific interactions. For more details the reader is referred to a review.

2.2 Separation Depending on the Membrane Protein Category

From a didactic point of view, proteins embedded in membranes may be divided on the basis of their biological role into receptors, glycosylated proteins, channel or carrier proteins, and structural proteins or those without a particular function.

The first consideration in defining the development strategy of an HPLC method is to establish whether the main interest is to isolate the protein functionally active or its characterization. In the former case nondenaturating conditions must be used, whereas in the latter case any type of detergent or organic eluent may be used for the optimum separation.

2.2.1 Cellular Receptors

In the case of rectorial proteins, they rarely exist in aggregated form and they are specific for recognizing a particular ligand. Thus nondenaturating size-exclusion chromatography (SEC) may not be used, and affinity chromatography is more indicated, because immobilized ligands proteins can be bound specifically and eluted selectively. The natural ligand might be an ideal choice for binding selectivity but may suffer from a high intrinsic binding affinity, which could lead to inactivation of the receptor or ligand due to the harsh conditions needed for release from the affinity support. Lectin affinity chromatography is largely used for glycoproteins and IA chromatography is the most widely used method for receptors.

A more practical ligand may be a monoclonal antibody (MAb) to the receptor, which can be preselected for modest affinity and appropriate binding kinetics (on and off rates). In general, to prepare an IA sorbent, MAB is preferred over polyclonal antibody, since the MAB can be obtained once a hybridoma clone has been isolated reproducibly, and second because the appropriate MAB can be selected with the desired binding properties to optimize biomolecular adsorption and elution. The desired elution conditions can be incorporated into the screening procedure to identify the most advantageous MAb. Since the binding constant varies from clone to clone, selection of a clone producing a MAb with a desirable binding constant is necessary. An antibody that gives a good response in either Western blot or enzyme-linked immunosorbent assay (ELISA) is not necessarily the best ligand for the IA sorbent. An example of this procedure is described in section 4.2.2. Interaction analysis using such current tools as optical biosensors can be used to screen MAbs for those with a good balance of sufficiently high affinity and finite off rate (see section 5). Many receptors have been separated by IA. A milestone in this field is the separation of transferrin receptor from plasma membranes of various mammalian cells. It is known that this protein binds with high affinity to immobilized dier ferric transferrin, whereas its affinity for apotransferrin is low. Consequently, the complex of transferrin and transferrin receptor can be dissociated by chelation of ferric ions after the addition of chelating reagents. In this way transferrin receptor can be eluted from the column under mild conditions.

2.2.2 Carriers or Channel Proteins Translocating Ions

Membrane proteins with the function of carriers or containing channels translocating ions across membranes may be separated and identified by the use of the perfusion planar lipid membrane (BLM) technique coupled with an HPLC system. This technique has been demonstrated to be efficient for the fast identification, isolation and characterization of transport proteins (porins) in the outer membrane of bacteria and other organisms, but it seems to be of general validity. The method is based on solubilization of the membrane, separation of solubilized membrane proteins into fractions (100–150) eluted from an HPLC column followed by immediate screening on the BLM for channel-forming activity, allowing precise localization of the porin-containing protein peak. The principle of the BLM method is simple. A planar lipid membrane interposed between two electrodes is predictably dull, showing little permeability to ions, no voltage dependence, and no interesting transport behavior. However, the introduction of a channel-forming protein, previously separated by HPLC, that is spontaneously incorporated into the bilayer dramatically alters the situation, allowing chemical substances to cross the lipid bilayer and giving rise to an ionic current. Furthermore, the opening and closing of this single ionic channel can be easily detected and modification of the channel properties by voltage, pH, ionic composition, blockers, mutation and chemical reagents can also be quantified. Although the BLM is an in vitro system, its validity has been demonstrated repeatedly through the more recent technique.
of patch clamping, giving confidence that what is measured using a BLM corresponds qualitatively and often quantitatively to what is observed in whole cells. BLMs have been intensively used in the identification and reconstruction of channel-forming proteins,\textsuperscript{10} to determine the deposition of amyloid proteins observed in Alzheimer’s disease pathology,\textsuperscript{11} and in the study of membrane proteins of other disease-related bacteria, whose porins or pathogenic toxins might be labile.\textsuperscript{9,10}

### 2.2.3 Glycoproteins

Determination of the carbohydrate composition, type, and branching pattern is an important step in understanding the biological function of glycoproteins and in the development of a recombinant DNA-derived glycoprotein as a pharmaceutical. Unfortunately, glycoproteins exist in a variety of biologically active forms, owing to the nature of the diversity of monosaccharides and the variety of possible linkages. It may be estimated that the linkage possibilities of a hexasaccharide yield a possible $4.76 \times 10^9$ structures.\textsuperscript{12}

The complexity of carbohydrate structures mandates that a variety of analytical methods be used for the study of these forms.

Lectin affinity chromatography is used to separate membrane glycoproteins, but a promising new procedure is described in section 4 that uses HPLC in conjunction with electrospray ionization mass spectrometry (ESIMS) as a tool to identify the sites of glycosylation and the general nature of the glycosylation. ESIMS can detect whether an oligosaccharide is O- or N-linked and can also differentiate between complex, high-mannose, and hybrid forms.

### 2.2.4 Others

When the membrane proteins that are to be analyzed do not play any functional role and their identification and characterization are the main aim, RPHPLC offers the best resolution of all chromatographic methods, especially when coupled on-line with a mass spectrometer. In sections 4 and 5 some aspects of this application will be presented and discussed.

### 3 CHROMATOGRAPHY OF LIPOPROTEINS

The term lipoprotein refers to particles which are heterogeneous with respect to size, hydrated density, and composition. The main function of the lipoprotein system is to transport lipids to surrounding tissues. All are made up of cholesterol, cholesterol esters, triglycerides, phospholipids, and apoproteins in varying proportions. Lipoproteins have a globular structure containing hydrophobic lipids such as triglycerides and cholesterol esters within the interior core, and a periphery containing more polar lipids, phospholipids, cholesterol, and proteins.

Owing to their strong heterogeneity, classification of lipoproteins remains undefined. Hydrated density is the more common form of lipoprotein classification. Thus lipoproteins are separated into very low-density lipoprotein (VLDL), low-density lipoprotein (LDL) and high-density lipoprotein (HDL) fractions. In this case, lipoproteins are viewed as particles which are heterogeneous with respect to their physical properties but homogeneous with respect to apolipoprotein composition. The HDL, LDL and VLDL groups show different functions, which results in their having different properties with respect to atherosclerosis, and therefore it is very important to have methods available for their separation.\textsuperscript{13} On the other hand, due to the growing evidence that apolipoproteins are better markers of coronary heart disease (CHD) than are serum cholesterol levels,\textsuperscript{14} and that the apolipoprotein distribution is important in diagnosing lipoprotein abnormalities, the separation and characterization of lipoproteins with respect to protein composition is of increasing interest. In Table 1 are summarized the physical and chemical properties of the main lipoprotein classes and their subfractions and also the different types of apoproteins and their isomers.

### 3.1 Methods for Lipoprotein Separation

As an alternative to ultracentrifuge separation, gel permeation separation does not require expensive ultracentrifugation instrumentation and has the advantage of being relatively mild and nondestructive in the separation

3.1.1 Separation by Particle Size and Subfractions

Gel permeation is normally used to separate lipoproteins on the basis of differences in particle size. It was initially performed on cross-linked dextran supports, which are able to withstand high pressures, decreased the separation time dramatically to 1 h compared with 20 h by the conventional gel permeation method. Furthermore, the separation may be easily automated, allowing unattended analysis of multiple samples. Automation also allows on-line monitoring of cholesterol in the separated LDL and HDL fractions (see later).

Two new emergent chromatographic techniques for lipoprotein separations are hydroxyapatite and countercurrent chromatography (CCC).

Their combined use allows a better separation and analysis of HDLs, LDLs and VLDLs from human serum without prior ultracentrifugation (see section 5).

3.1.2 Separation of Apolipoprotein and Isomers

Affinity chromatography, which employs specific and reversible interactions between lipoprotein and bound ligands, is capable of separating lipoproteins on the basis of their apolipoprotein content. Affinity chromatography of lipoproteins can be performed using group-specific or biospecific ligands. Group-specific ligands include concanavalin A, which binds to apoB-containing lipoproteins, and heparin, which interacts specifically with apoB and apoE, while antibodies to specific apolipoproteins serve as biospecific ligands in IA chromatography. This technique provides the highest specificity for the separation and isolation of lipoproteins on the basis of their apolipoprotein content, while group-specific ligands are more economically convenient but the separation is less accurate.

In addition to affinity chromatography, the high-performance gel permeation, ion-exchange or reversed-phase mode may be used to separate apolipoproteins into their isomers. Unfortunately, in these HPLC systems only small amounts of sample (<5 mg) can be applied to the column. However, the speed (<60 min) and ease of operation make these techniques ideal for the analytical separation and characterization of apolipoproteins. GPC is often used as a preparative technique for isolating apolipoproteins derived from HDL or VLDL, while separation of isoforms can be achieved by either ion-exchange or RPHPLC. Apolipoproteins from HDL and VLDL can be separated in less than 60 min on high-performance TSK gel permeation columns. Separations of apolipoproteins by ion-exchange chromatography are based on differences in charge. Therefore, this mode of chromatography can separate apolipoproteins with different isoelectric points. In contrast, differences in hydrophobicity are the basis of separation by RPHPLC. The reversed-phase columns usually have a lower sample capacity (<100 mg) than those used in gel permeation HPLC. Moreover, the column lifetime is relatively short, owing to the instability of silica-based stationary phases at pH extremes. However, there is growing interest in the use of RPHPLC as a rapid and highly efficient technique for monitoring heterogeneity in apolipoprotein structure.

4 APPLICATION EXAMPLES

As mentioned above, the separation of membrane proteins and lipoproteins will be presented separately owing to the specificity of the methods set up for the two main protein categories. However, in both cases HPLC is the most convenient method used, and therefore a few considerations specifically relevant to the instrumentation required are presented.
4.1 Experimental Considerations

In the case of proteins, more than for small organic compounds, HPLC requires extremely precise control of the solvent composition, because the RPHPLC elution time is much more dependent on organic solvent composition. Single-pump, low-pressure mixing HPLC gradient systems are widely used for protein analysis. However, when using solvents that are difficult to mix (e.g. 1-propanol), dual-pump, high-pressure mixing is advantageous because the two solvent streams are delivered continuously rather than delivered in a segmented fashion. Moreover, with single-pump operation the continuous sparging of solvents with helium, for degassing purposes, results in changes to the organic solvent composition. This problem may be minimized by presaturation of the helium with organic vapor by passing the sparge gas through a solvent reservoir containing the mobile phase.

With respect to detection, generally either 280- or 214-nm wavelengths are employed for protein analysis. Detection at 214 nm is more sensitive and more generally applicable because absorption at this wavelength is due to the peptide backbone. However, some HPLC mobile-phase constituents may interfere at this wavelength (e.g. acetate salts). Detection at 280 nm is somewhat less sensitive, but can be used to detect most proteins (absorption at 280 nm is primarily due to the aromatic amino acid side chains of tryptophan, phenylalanine and tyrosine). In some cases, dual-wavelength or diode-array detectors are recommended in order to provide more detailed spectral information for each peak observed.

In general, the sample solution should be similar in composition (e.g. pH) to the HPLC mobile phase so as to minimize the effect of the sample injection on the separation efficiency. One exception to this rule is RPHPLC, where the organic solvent composition of the sample should be less than that of the initial mobile phase in order to focus the injected proteins at the head of the column. Clearly, the protein must have adequate stability in the selected solvent and in many cases stability must be enhanced by use of a refrigerated autoinjector. When conducting size-exclusion HPLC for determining noncovalent multimers, one must avoid the use of denaturants (e.g. organic solvents) or extreme pH conditions that might disturb the equilibrium between monomer and multimer forms.

Clearly the column is the heart of the HPLC separation system. Unfortunately, this is the one component over which the analyst has the least direct control. Consequently, it is important to work closely with the column manufacturer to obtain several independent column manufacturing batches, and to investigate whether a particular method performs consistently on a number of such batches. Whenever possible, an HPLC method to be used on a routine basis should be validated using two alternative sources (brands) of columns, in order to minimize the impact of column manufacture problems.

The advent of new reversed phases such as C-4 allowed excellent separations of hydrophobic proteins with a high protein recovery (see later). The use of microbore HPLC and packed capillary HPLC for characterizing biosynthetic proteins is becoming more widespread. However, such techniques have not been widely adopted for routine use or method development within the laboratory owing to limitations on hardware and the relatively large amounts of assay material available. As hardware advances occur, this situation may change because the advantage of lower solvent consumption is clearly attractive. Furthermore, such techniques are more compatible with high-performance liquid chromatography/mass spectrometry (HPLC/MS) systems, which are now widely available and offer profound advantages for method development (see section 5).

4.2 Membrane Proteins

Here three examples are presented.

4.2.1 Cellular Receptor

CD4 is an integral membrane glycoprotein of T cells that acts as the cellular receptor for human immunodeficiency virus (HIV). Many protocols have been set up to recognize and separate CD4. All are based on IA, using monoclonal antibodies and autoantibody directed against conformational epitopes of CD4.

4.2.1.1 Selecting a Monoclonal Antibody

Soluble CD4 (sCD4) has been considered as a possible therapeutic agent for acquired immune deficiency syndrome (AIDS) by acting as a molecular decoy, i.e. by binding to the gp120 coat protein of HIV and thereby preventing cellular binding of HIV. Consequently, there is a growing interest in searching CD4 variants from either mammalian cell culture or microbial extracts, showing improved pharmacokinetic properties. A rapid generic purification scheme for sCD4 constructs has been developed using IA separation. To prepare a robust IA sorbent for the purification of sCD4, a number of sCD4 mutants and a series of MAbs were examined. Five different commercial anti-CD4 monoclonal antibodies were immobilized through protein amino groups on to a Sepharose matrix containing an 11-atom spacer using active ester chemistry and all of the sorbents were evaluated individually on a small test column. Figure 1 shows representative chromatograms to illustrate that different antibodies bind CD4 differently.
In the cases of L-92.5 and L-83 clones, the binding was restrictively tight, whereas L-71, L-77, and L-104.5 showed moderate and more tractable binding affinity. Although L-92.5 sorbent bound the highest amount of CD4, the recovery was the least of all the sorbents. On the other hand, the L-71 sorbent showed moderate binding but the recovery of sCD4 was quantitative. Thus, MAb L-71 was judged to be the most suitable candidate for immobilization to prepare an affinity sorbent to purify CD4 and a scale-up IA sorbent to purify CD4 congeners.

Using this antibody as IA sorbent, recombinant proteins loaded on the column were recovered with very high yield using elution with 0.1 M acetic acid. The proteins recovered formed an electrophoretically homogeneous product and after neutralization were highly active with respect to gp120 binding, as judged by a radioligand-bead binding assay. The sorbent was also used successfully to purify full-length CD4 in highly active form.

4.2.2 Red Blood Cell Membrane

Molecular masses of the proteins contained in red blood cells membrane range between 20 and 200 kDa, and consequently the most common HPLC techniques used for the purification of these proteins are based on SEC (which may be used in the presence of either ionic or nonionic detergents) and, to a lesser extent, on ion-exchange or hydrophobic interaction chromatography (compatible with nonionic detergents). We have used a reversed-phase C-4 column for the separation of epitope on the surface of domain 1 of CD4. IA chromatography was used to purify both sCD4–183, consisting of the N-terminal 183 amino acids of human CD4, and sCD4–PE40, a fusion protein consisting of the N-terminal 178 amino acids of CD4 and amino acids 1–3 and 253–613 of Pseudomonas exotoxin A (PE40). Relatively high recoveries of sCD4–183 and sCD4–PE40 were observed in the IA step of the purification process (71 and 79% recovery, respectively). sCD4–183 was purified from E. coli cell pellets using cell disruption, protein solubilization, oxidation, Q-Sepharose anion-exchange and IA chromatography steps. sCD4–PE40 was purified from cell pellets using cell disruption, protein solubilization, oxidation, Cu²⁺ immobilized metal-affinity chromatography, anion-exchange and IA chromatography steps. The immobilized MAb appeared to select for correctly folded CD4 protein, since sCD4–183 and sCD4–PE40 purified by the IA method bound HIV glycoprotein gp 120 (HIV gp 120) in vitro. The results demonstrate that immobilized monoclonal antibodies directed against conformational epitopes may be used for the rapid purification of gram amounts of correctly folded protein from mixtures of oxidized E. coli proteins.

![Figure 2](image_url)
membrane proteins from erythrocyte ghosts using mobile phases containing acetonitrile and 0.1% TFA. The erythrocytes were swollen by 5 mM Na₂HPO₄ isotonic solution and after several centrifugations at 3000 g the pellet was solubilized in two volumes of pure acetonitrile. Samples were loaded directly on the column without any other manipulation. Figure 2 shows the chromatogram obtained using a gradient of acetonitrile.

A silica-based C-4 column eluted with TFA–acetonitrile is a perfect combination for several polypeptide separations, but was considerably less suitable for membrane protein separation than a resin-based phenyl column eluted with the same mobile phase. In our case, better separation is related to the absence of detergent during the extraction and elution run and probably also to the better quality of resin in the column.

4.2.3 Separation of Photosynthetic Proteins from the Thylakoid Membrane of Chloroplasts

In this section we present the results of a study performed to develop a rapid and straightforward HPLC method to resolve and identify the protein components of PSI and PSII. These two large complexes, of at least 40 proteins, are present in the thylakoid membrane of chloroplasts (Figure 3) and have the main role of capturing the light and giving the necessary energy to transfer electrons from water to nicotinamide adenine dinucleotide phosphate (NADP) via the two photosystems, PSI and PSII, and a number of electron carriers.

PSII is embedded in the thylakoid membrane and contains a reaction center (core) of 21 large and smaller proteins, surrounded by a specific light-harvesting system, which is the major protein–chlorophyll a–b complex [light-harvesting complex of photosystem II (LHCII)] and minor antennas called CP29, CP26 and CP24.²⁹ In contrast, structural information on PSI at the atomic level is lacking.

The proteins associated with PSI and PSII have been traditionally resolved by SDS/PAGE into several closely related hydrophobic membrane proteins, typically in the range 21–40 kDa.³⁰ The uncertainty of the number of proteins in the complex is mainly due to the different procedures and detergents used to solubilize PSI and PSII from the thylakoid membranes and to the different methods employed in isolating and characterizing the individual membrane proteins in the complex. The antenna proteins show amino acid compositions similar in length and sequence,³¹ and therefore the characterization of these proteins is performed by tedious electrophoresis and immunoblotting, which require run times of 20–30 h.³² Traditional approaches by SDS/PAGE are not only cumbersome but also rather ineffective for evaluating differences in the relative quantity of each LHCII component. We have set up a high-performance separation technique for the resolution of thylakoid membrane proteins employing a reversed-phase Vydac Protein C-4 column containing 5-µm pores.³³

4.2.3.1 Preparation of Photosystem I and Photosystem II

In Figure 4 are summarized the main steps to separate the PSI and PSII present in the thylakoid membrane.

---

Figure 3 Organization of proteins contained in the thylakoid membrane and involved in photosynthesis. (Reproduced by permission of Professor J. Barber, Imperial College, London.)
Figure 4 Separation scheme for PSII and PSI.

Chloroplasts were isolated from spinach leaves according to the method of Berthold et al.\textsuperscript{(34)} with the following modifications. Leaves were powdered in liquid nitrogen and subsequently homogenized in an ice-cold 20 mM tricine buffer (pH 7.8) containing 0.3 M sucrose and 5.0 mM magnesium chloride (buffer B1). The homogenization was followed by filtration through one layer of Miracloth (Calbiochem, San Diego, CA, USA).
and centrifugation at 4000 g for 10 min at 4 °C. Pellets were suspended in buffer B1 and centrifuged as above. These second pellets were resuspended in 20 mM tricine buffer (pH 7.8) containing 70 mM sucrose and 5.0 mM magnesium chloride (buffer B2) and centrifuged at 4500 g for 10 min. Pellets containing the thylakoid membranes were then resuspended in 50 mM morpholinooethanesulfonic acid (MES) buffer (pH 6.3) containing 15 mM sodium chloride and 5 mM magnesium chloride (buffer B3) at 2.0 mg mL\(^{-1}\) chlorophyll for 15 min after adding Triton X-100 at a final ratio of 20 mg mg\(^{-1}\) chlorophyll. The concentration of chlorophyll was determined according to the method described by Porra et al.\(^{35}\) The incubation was terminated by centrifugation at 40 000 g for 30 min at 4 °C. This pellet containing the PSII complex and corresponding to the BBY preparation described by Berthold et al.\(^{34}\) was resuspended in buffer B3 containing 20% (v/v) glycerol and stored at \(-80^\circ\)C.

4.2.3.2 Subfraction of Photosystem II by Sucrose-gradient Ultracentrifugation

PSII membranes, once isolated from thylakoid membranes, were then subjected to sucrose-gradient ultracentrifugation in order to isolate the protein components of the minor antenna system (band 2) from the major (band 3) and also from the reaction-center complexes (bands 4–5). With this aim in mind, PSII membranes were pelleted by centrifugation at 10 000 g for 5.0 min at 4 °C, suspended in buffer B3 at 1.0 mg ml\(^{-1}\) chlorophyll and then solubilized by adding 1% (w/v) β-DM. Unsolubilized material was removed by centrifugation at 10 000 g for 10 min. The supernatant was rapidly loaded on to a 0.1–1.0 M sucrose gradient containing buffer B3 and 5.0 mM β-DM. The gradient was then spun on a Kontron (Milan, Italy) Centricon T-1080 ultracentrifuge equipped with a TST 41.14 rotor at 39 000 rpm for 18 h at 4 °C. Green bands were harvested with a syringe. The SDS/PAGE analysis of these green bands revealed that band 3 contained essentially LHCII proteins, as reported previously by Bassi and Dainese.\(^{37}\) Consequently, this was the purified starting material used for the HPLC study.

4.2.3.3 Separation of Photosystem II Proteins by Reversed-phase High-performance Liquid Chromatography

In this study we searched for the conditions to resolve the protein components of the major and the minor antenna system of PSII either as the complex isolated by sucrose-gradient ultracentrifugation and as assembled in the grana membrane (BBY particles), using either an analytical (250 × 4.6 mm ID) or a semipreparative (250 × 10 mm ID) sized column, both packed with the same 5-µm spherical Vydac C-4 stationary phase. The use of a semipreparative sized column was needed in order to obtain an amount of purified polypeptide sufficient for peak identification by SDS/PAGE, immunoblotting, and amino acid microsequencing. The optimum separation of the protein components of the PSII antenna system was obtained by the following procedure.

The Vydac C-4 columns were preequilibrated with 38% (v/v) aqueous acetonitrile solution containing 0.1% (v/v) TFA and samples were eluted using either gradient I or II, depending on the HPLC unit employed for the separation. Gradient I consisted of a first linear gradient from 38 to 55.4% (v/v) acetonitrile in 22 min, followed by 3 min of isocratic elution with the eluent containing 55.4% acetonitrile, followed by a second gradient segment from 55.4 to 61.8% (v/v) acetonitrile in 8 min and by a third gradient segment from 61.8 to 95% acetonitrile in 1 min. Gradient II consisted of a first linear gradient from 38.0 to 61.8% (v/v) acetonitrile in 40 min, followed by a second gradient segment from 61.8 to 95% (v/v) acetonitrile in 1 min. For both gradients the last gradient segment up to 95% acetonitrile was used for washing out hydrophobic contaminants of the PSII antenna system from the column. Gradient I was used to elute either the analytical or the semipreparative column. The flow rate was 1.0 mL min\(^{-1}\) with the analytical column and 4.7 mL min\(^{-1}\) with the semipreparative column. These conditions were selected in order to maintain the same gradient shape with both columns by keeping the ratio of the gradient volume to the column volume constant.

The chromatogram displayed in Figure 5(a) shows that the material harvested from the second band of the sucrose-gradient ultracentrifugation, containing a mixture of the protein components of both the major and the minor PSII antenna system, was resolved into eight main peaks. Five of these peaks, with corresponding retention times, were also obtained on separating, under the same conditions, the material harvested from the third band of the sucrose-gradient ultracentrifugation (Figure 5b), containing essentially the protein components of the major PSII antenna system. From these data it can be inferred that the peaks labeled 1, 2, 5, 6 and 7 correspond to components present in both the sucrose bands 2 and 3, whereas peaks 3, 4 and 8 are essentially due to the component present only in the sucrose band 2, which can be tentatively identified with the minor antenna complexes CP29, CP26, and CP24.\(^{38}\) Figure 5(c) shows the chromatogram of BBY injected on the column directly, avoiding the separation step by sucrose-gradient ultracentrifugation. It can be observed that upon injection of BBY directly, the protein components of the PSII major and minor antenna system are well resolved without interference from the other protein components of PSII. Therefore, the use of the crude PSII membrane preparation does not affect the resolution and retention times, while new and smaller peaks appear at longer elution times. The
new peaks, observed in Figure 5(c), represent the core proteins, which are more hydrophobic and elute at higher concentrations of acetonitrile (data not shown).

In order to assign to each HPLC peak a name of the well known antenna proteins, SDS/PAGE systems employing different buffer systems and either Coomassie Brilliant Blue or silver staining followed by immunoblotting detection with antisera directed to the individual antenna proteins were performed, in addition to amino acid microsequence analysis of the material collected throughout the chromatogram.

In the case of SDS/PAGE and immunoblotting, each fraction collected from the semipreparative chromatographic separation lyophilized, were dissolved in 120 mM tris(hydroxymethyl)aminomethane (TRIS)–HCl buffer (pH 8.45), containing 120 mM dithiothreitol (DTT), 5M urea and 4% (w/v) SDS, and then analyzed by SDS/PAGE, according to the method reported by Shaeberger and von Jagow[39] (Figure 6a).

Following electrophoresis, the gels were either silver stained or transferred to nitrocellulose. Replicates were assayed with antisera directed to LHCII, CP29, CP26, and CP24[40] (Figure 6b–d). Because of the high degree of homology shared by all of the antenna polypeptides, it was essential for identification of the fractions to take into account both the immunoreactivity and the electrophoretic mobility of the SDS/PAGE bands. In TRIS/Tricine electrophoresis, antenna proteins migrate in the following order of increasing mobility: CP29 > CP26 > LHCII > CP24 and, within LHCII, Lhcb1 > Lhcb2 > Lhcb3[41]. Accordingly, the slower migrating band was detected by the anti-CP29 in peak 4 (Figure 6b), while peak 8, containing a slightly more mobile band, was recognized by anti-CP26 (Figure 6c). The anti-CP24 detected several bands (Figure 6d) but the strongest signal, with respect to the intensity of the band in the silver stained gel, was obtained with the most mobile band in peak 3. Therefore, peaks 3, 4 and 8 seem to contain CP24, CP29, and CP26, respectively. The higher hydrophobicity of CP26 agrees with the longer elution time required.

Thus, according to the migration order of increasing mobility reported above, the fastest migrating band was recognized as Lhcb3, the second fastest migrating band as Lhcb2, and the two newly resolved bands as Lhcb1 components of LHCII.

From the above data, we conclude that peak 1 does not contain protein components; peak 2, the Lhcb2 component of LHCII; peak 3, the CP24 (Lhcb6); peak 4, CP29 (Lhcb4); peaks 5 and 6, two Lhcb1 components of LHCII; peak 7, Lhcb3; and peak 8, CP26 (Lhcb5).

In order to support the identification previously assigned, the protein contained in each HPLC peak was subjected to amino acid microsequencing and compared with amino acid sequences reported in the literature for other species (data not shown). Good agreement with the above assignment was found.

Finally, the assignment of each peak resolved by RPHPLC performed by electrophoresis, immunoblotting, and amino acid sequencing is corroborated from the values of molecular masses determined by the combined use of microbore HPLC coupled on-line with a mass spectrometer[42] equipped with an electrospray ion source (see section 5).

From the results presented, it can be inferred that the major antenna system of PSII isolated from spinach leaves contains two different Lhcb1 proteins which can be resolved by the RPHPLC system employing a 250 mm long Vydac C-4 column eluted with a multisegment acetonitrile gradient, as well as by the high-resolution
TRIS/Tricine SDS/PAGE system in gels of 15 cm length (data not shown). On the other hand, the small microsequence performed does not reveal any amino acid differences and the molecular mass measured by mass spectrometry (MS) indicates that the difference is of the order of 60–80 kDa. More experiments and a complete amino acid sequence are necessary to give an explanation for these different subpopulations of Type I. Nevertheless, the existence of more type I LHCII is in accordance with molecular genetic data reported in the literature showing that higher plants have several Lhcb1 genes encoding different Lhcb1 proteins for each species. However, it is important to note that the resolution by SDS/PAGE of two Lhcb1 proteins usually requires special experimental conditions such as the use of polyclonal and monospecific antibodies, dedicated electrolyte solutions, and a gel of extended length, whereas using HPLC the two different subpopulations may be easily separated.

The RPHPLC method reported here, in addition to being rapid, simple, and precise, has proven to be effective at detecting differences in the protein components of LHCII isolated from different plants that might be not evidenced by denaturing SDS/PAGE, as in the case of Type I of spinach. This knowledge is expected to shed light on the composition and supramolecular organization of LHCII and may increase the understanding of the molecular mechanisms underlying the physiological adaptations of higher plants to environmental conditions.

4.2.4 Separation of Proteins Present in Photosystem I

PSI prepared from the thermophilic cyanobacterium *Synechococcus elongatus* has been crystallized and the structure determined at a resolution of 6 Å. The determination of the structure of higher plant PSI has been less successful, most likely because it is a much larger complex than its cyanobacterial counterpart. The...
cyanobacterial PSI complex consists of 11 subunits.\(^\text{46}\) In the case of higher plants, although a lot of PSI genes have been identified and sequenced, there is little information on the protein, and the relationship between the gene and relative protein expressed is lacking. This is related to the fact that the molecular masses of most of these proteins range between 4 and 25 kDa, and consequently they are not well separable by SDS/PAGE.

4.2.4.1 Isolation of Photosystem I by Sucrose-gradient Ultracentrifugation  
Supernatants of the first purification were concentrated by ultrafiltration and then solubilized by \(\beta\)-DM at a final concentration of 1\%. After stirring for 20 min at 4 \(^\circ\)C, the sample was centrifuged for 10 min at 40 000 \(g\), and 6-mL aliquots of the supernatant were loaded on 0.1–1 M sucrose gradients (35 mL) layered over 2 mL of 2 M sucrose, containing 5 mM Tricine (pH 7.8) and 0.03\% \(\beta\)-DM. After centrifugation for 42 h at 28 000 rpm in an SW28 rotor (Beckman) at 4 \(^\circ\)C, four green bands were distinguishable. The bands were collected and analyzed by SDS/PAGE.\(^\text{47}\) The lowermost band, containing PSI-200, was diluted in 5 mM Tricine (pH 7.8) and centrifuged for 3 h at 70 000 rpm in an 80 Ti rotor (Beckman). The pellet was resuspended in 5 mM Tricine (pH 7.8) and 50 mM sorbitol, frozen in liquid nitrogen, and stored at \(-80^\circ\)C.

4.2.4.2 Purification of Photosystem I Core and Light-harvesting Complex of Photosystem I  
The pellet from PSI-200 preparation was resuspended at 0.3 mg mL\(^{-1}\) in distilled water and solubilized by 1\% \(\beta\)-DM and 0.5\% Zwittergent-16. After stirring for 20 min at 4 \(^\circ\)C, the sample was rapidly frozen in liquid nitrogen and slowly thawed to improve the detachment between the PSI core and the light-harvesting complex of photosystem I (LHCI). Samples (1.5-mL aliquots) were loaded on a 12-mL 0.1–1 M sucrose gradient, also containing 5 mM Tricine (pH 7.8) and 0.03\% \(\beta\)-DM. After centrifugation for 24 h at 4 \(^\circ\)C at 41 000 rpm in an SW41 rotor (Beckman), five green bands were obtained. The bands were analyzed by SDS/PAGE.\(^\text{47}\) The second band from the top contained all of the LHCI polypeptides and the third the PSI core particles. The fractions were frozen in liquid nitrogen and stored at \(-80^\circ\)C.

4.2.4.3 Separation of Photosystem I Proteins by Reversed-phase High-performance Liquid Chromatography  
The complete resolution of the protein components of the PSI was performed by RPHPLC as for PSII. The experiments were carried out subjecting to chromatography all proteins of PSI-200 and then separately the antenna and core proteins previously isolated by sucrose-gradient ultracentrifugation.

![Figure 7](image-url)
of the protein components of the PSI antenna system, is resolved into five main peaks (Figure 7a). Most of the peaks are symmetrical, but the last one at 43.4 min is broad, indicating the presence of more than one protein. In contrast, the material harvested from the third band of the sucrose-gradient ultracentrifugation, containing essentially the core protein components of PSI, shows a main peak at a long elution time of 61 min, and numerous smaller peaks. The main peak is broad and elutes at a long time, suggesting the presence of more than protein showing high hydrophobicity. Finally, in the chromatogram for the total PSI-200, five of the same peaks with retention times corresponding to those observed in Figure 7(a) are present, which are the most abundant separated proteins and allow one to hypothesize that they represent the antenna complex, although only four proteins are expected. Moreover, the main peak observed in the core complex (Figure 7b) is also observed in Figure 7(c), which may be hypothesized to contain psaA and psaB, and other smaller core peaks are underestimated when all proteins are present.

Once the optimized conditions to obtain a better separation of each component had been found, we attempted the identification of each protein contained in each peak by coupling on-line HPLC with MS (see section 5). The mass values measured by ESIMS corresponded to the molecular mass expected on the basis of the DNA sequence, allowing the assignment of each peak as reported in Figure 7(c). These results corroborate the utility of on-line coupled HPLC/MS with an electrospray ion source.

Finally, the separation of both PSI and PSII may be achieved by direct injection of thylakoid membrane into the column and elution with a multisegmented gradient. All the protein components of the PSII can be well resolved without interference from the other protein components of PSI, indicating that the use of the crude thylakoid membrane preparation does not affect the resolution and retention times of each protein.

4.3 Separation of Lipoproteins

4.3.1 Preparation of Lipoprotein Fractions

Plasma or serum can be used for lipoprotein analysis. However, plasma is preferred since it can be kept cold in order to slow most enzymatic processes that degrade lipoproteins. The following procedure is commonly used to prepare lipoproteins. Human blood (ca. 20–30 mL) was collected from normolipidemic males by venepuncture after 12–16 h of fasting. The blood was allowed to stand for 2–3 h at room temperature until agglutination was complete. The plasma was withdrawn after centrifugation at 1000g at 15°C for 15 min. The plasma density was adjusted to 1.225 g mL⁻¹ by adding solid potassium bromide (0.3517 g KBr per milliliter of plasma). Plasma (1.225 g mL⁻¹, ca. 3–5 mL) was then placed in ultracentrifuge tubes, which were centrifuged in a swinging-bucket rotor at 200000 g at 10°C for 40 h. The lipoprotein fraction prepared by this procedure did not contain serum proteins, except for a small amount of albumin. The lipoprotein fraction in the KBr solution was dialyzed against 0.154 M sodium chloride solution.

4.3.2 Preparation of Individual High-density Lipoprotein, Low-density Lipoprotein and Very Low-density Lipoprotein Fractions

Many separations subfractionate the lipoprotein fraction of plasma. Hence each main class of lipoproteins may be collected by ultracentrifugation using a multiple discontinuous density gradient. For this purpose, human blood was collected from fasting normolipidemic healthy males in tubes containing 0.15% EDTA. The plasma was separated by centrifugation at 700 rpm at 7°C for 20 min. A discontinuous NaCl–KBr density gradient (total volume 18.5 mL) was formed by adjusting the density of plasma to 1.30 g mL⁻¹ with solid KBr and sequentially layering on the adjusted plasma salt (NaCl–KBr) solutions with densities of 1.240, 1.063, 1.019 and 1.006 g mL⁻¹ and 0.5 mL of distilled water. Tubes loaded with the discontinuous density gradient were placed in a vertical rotor and centrifuged at 313 500 g at 7°C for 80 min.

4.3.3 Separation of Particles and Subfractions

In an alternative to ultracentrifuge separation, the GPC mode of HPLC is the most commonly used method to separate particles such as HDL, VHDLO and LDL. Two commercial columns are commonly used: Superose 6 (from Pharmacia) and TSK-type. Rigid, fast-flow agarose gels, such as Superose 6, are able to accept large sample volumes (up to 5 mL) and it is preferred for the preparation of larger quantities of plasma lipoproteins. Furthermore, multiple automated separations of lipoproteins from whole plasma may be performed with a preparative-grade Superose 6 column. Thus 2 mL of plasma are loaded and eluted with 0.9% sodium chloride and 2 mM sodium phosphate (pH 7.4). The eluent also contains 0.02% or 1% sodium azide for serum or plasma separation, respectively. VLDL, LDL, and HDL can be separated in a single run. A single separation can be completed in about 160 min. Hence the system can be used to analyze up to six different plasma samples (2 mL per sample) overnight.
Figure 8. Chromatographic profile of normal and HLP sera. Conditions: 300-mm Superose 6 column eluted with 100 mM Na₂HPO₄, 200 mM NaCl (pH 7.4) at 300 mL min⁻¹. (a) Normolipidemic sample; (b) Type IIa HLP; (c) Type III HLP; (d) Type IV HLP. Peaks from left to right: VLDL, LDL, HDL. (Reproduced by permission of Clinical Chemistry from W. Marz, R. Skeimer, H. Scharnagl, U.B. Seiffert, W. Gross, Clin. Chem., 39(11), 2276–2281 (1993).)

Figure 9. Stepwise elution profile of human serum lipoproteins. Column, Bio-Gel HTP DNA grade 25 1.0 cm ID; eluents, 25, 200, 300 and 650 mM potassium phosphate buffer (KPi) (pH 7.4), flowrate, 12.0 mL h⁻¹, sample, 2.0 mL of human serum. (Reproduced by permission of Elsevier Science from Y. Shibusawa, J. Chromatogr. B, 699, 419–437 (1997).)

Fast-flow separation of plasma is also used, where lipoproteins are detected on-line at 500 nm after post-column derivatization with an enzymatic cholesterol reagent (CHOD-PAP, Boehringer Mannheim). The eluting lipoproteins and the cholesterol reagent are mixed in a chamber attached to the column outlet. The mixture is then passed through a reaction capillary and detected. Complete separation of lipoprotein fractions is usually achieved in less than 80 min. The chromatographic profiles of normal and several types of hyperlipoproteinemmic (HLP) serum samples are illustrated in Figure 8(a–d). The three peaks correspond to, in order, VLDL, LDL, and HDL.¹⁷

Separation of lipoproteins by HPLC on TSK-type gel permeation columns is faster than on a Superose 6 column but smaller sample volumes (<300 µL) may be loaded. Furthermore, serum instead of plasma is preferred for TSK-gel HPLC of lipoproteins. With plasma there is a
danger of fibrin forming during the analysis. A further disadvantage of the TSK method is that this type of column is generally more prone to clogging than a Superose 6 column. Adsorption of lipoproteins on the support has also been noted by some workers. It was found that a combination of G4000 SW and G3000 SW eluted with 0.15 M NaCl (pH 7) was best at separating serum lipoproteins into VLDL, LDL, HDL2 and HDL3. Separation by a TSK column allows the determination of lipids using a combination of two TSK columns and online enzymatic reaction. The system used two detectors. The first was placed immediately after the column and monitored protein absorbance at 280 nm. The second detector was placed after the enzymatic reactor and detected lipid absorbance at 500–600 nm.

Separation of large amounts of LDLs and VLDLs from human serum may be performed by using a hydroxyapatite Bio-Gel HTP DNA grade column (25 cm) or four stepwise elutions. In the latter case, a 2-mL volume of human serum is loaded on the column and eluted with a discontinuous gradient of 75, 200, 300 and 650 mM potassium phosphate buffer at pH 7.4. Figure 9 shows the elution profile of human serum obtained with a hydroxyapatite column.

Four peaks are detected, the first containing HDLs and serum proteins, the second the serum proteins, eluted at 200 mM, the third mainly LDLs, eluted at 300 mM, and the fourth VLDLs, eluted at 650 mM.

The whole lipoprotein fraction (d < 1.21) can be further subfractionated into VLDL, LDL and HDL by GPC. Lipoprotein fractions prepared by ultracentrifugation are often used for this further chromatographic separation. In this way, the procedure is both analytical and preparative, since the isolated fractions contain no contamination from serum proteins.

Subfractionation of HDL particles accomplished by GPC gives rise to subfractions having different sizes (3.81–528 nm) and different concentrations of proteins: HDL2a, HDL2b, HDL3a, and HDL3b. HDL particles may also be subfractionated by heparin affinity chromatography according to the apoE content. HDLs rich in apoE were separated into five subfractions using an elution buffer with varying Mn2+ concentration.

In the case of LDL, charge heterogeneity was demonstrated by ion-exchange chromatography. These types of separations are important since oxidatively modified LDLs have been associated with atherosclerosis. LDL particles modified by Cu2+ were analyzed by anion-exchange chromatography using a Mono Q HR 515 column (Pharmacia). Five different oxidatively modified LDLs were identified. The isolated fractions exhibited differences in density and lipid content.

### 4.3.4 Separation of Apolipoproteins and Isomeric Forms

The growing evidence that apolipoproteins are better markers of CHD than serum cholesterol levels has increased the interest in analyzing lipoproteins according to the apolipoprotein compositions.

Affinity chromatography, which employs specific and reversible interactions between lipoproteins and ligands, is capable of separating lipoproteins on the basis of their apolipoprotein content by using nonspecific binding and IA. Heparin was successfully immobilized on to glycyril controlled-pore glass (CPG) and used to bind specifically β-lipoproteins (apoB). Serum samples applied to heparin–CPG were separated into two fractions. The unretracted fraction was washed through the column with 0.1 M NaCl and the retained fraction was eluted with 1 M NaCl. Radial immunodiffusion studies confirmed the complete resolution of apoA- and apoB-containing lipoproteins. However, attempts at incorporating the heparin–CPG column into a high-performance affinity chromatography system were unsuccessful. Two types of lipoproteins have been clearly established as atherogenic, the apoB100-containing LDL and apoB48-containing chyomicron remnants. Human genetic disorders resulting in increased circulating levels of either of these lipoproteins cause premature atherosclerosis. Experiments were reported to demonstrate that the NH2-terminal region of apoB binds to heparin affinity gels with an affinity equal to or greater than that of apoB100-containing LDL. In addition, apoB48-containing lipoproteins were observed to bind to heparin as well as LDL. Hence, based on these findings, it was proposed that NH2-terminal apoB contributes to the atherogenicity of LDL and remnant lipoproteins.

Dextran sulfate is a synthetic analog of heparin, and also binds preferentially to apoB-containing lipoproteins. Commercial sulfated dextran beads from Sigma consist of sulfated cross-linked dextran and are useful for rapid (15 min) separation of apoA- and apoB-containing lipoproteins on elution of proteins by NaCl at 80 mM.

IA chromatography provides the highest specificity for separation and allows the separation of relatively large volumes (1–10 mL) of whole plasma or lipoproteins. Preparations of both polyclonal and monoclonal antibodies to apolipoproteins, produced using purified delipidized apolipoproteins, are commonly used as antigens. Antibodies to apolipoproteins coupled to cross-linked dextran (Sephadex) or agarose derivatives (Sepharose) serve as selective ligands for the separation of lipoproteins by IA chromatography.

Separation of apoproteins into their isomers is of interest especially for apoA and apoB, which may be performed by sequential chromatographic stages using more
IA or affinity followed by gel permeation, ion-exchange or reversed-phase techniques. In the first procedure, whole plasma is first fractionated into apoB and apoA lipoproteins by affinity chromatography on concanavalin A (con A). Further subfractionation proceeds by subsequent IA chromatography using a specific antibody: anti-apoA-II immunosorbent, which retains a fraction containing lipoprotein (A-1 + A-II) and lipoprotein A-II. Further, separation of this fraction on an anti-apoA-I immunosorber leads to the isolation of three types of apoA lipoproteins: lipoprotein A-1, lipoprotein A-II and lipoprotein (A-I + A-TI). Conventional GPC or ion-exchange chromatography on soft gel supports can be used for the preparation of large quantities (10–50 mg) of pure apolipoproteins, whereas by HPLC only small amounts of sample (<5 mg) can be applied to the column but the analysis is completed within 60 min. Separation by high-performance GPC is strongly dependent on the completeness of the delipidation step, which may be performed satisfactorily with an organic solvent. However, high-performance GPC separation of HDL apolipoproteins has been achieved without prior organic solvent delipidation of the HDL fraction.

GPC is often used as a preparative technique for isolating apolipoproteins derived from HDL or VLDL, while HDL apolipoproteins, apoA-I, apoA-II, and apoC, can be separated on Sephadex G-200 columns using TRIS–HCl buffer (pH 8.6) containing 8 M urea. ApoC and apoE from VLDL can be isolated by Sepharyl S-200 (Pharmacia) chromatography. Separation of apolipoprotein isoforms can be achieved by either ion-exchange or RPHPLC. ApoC isoforms (C-IIIb, C-III1, and C-III2) can be separated on Mono Q-HR 5/5 (Pharmacia) anion-exchange columns in less than 30 min using a linear gradient of 0.15 M NaCl in TRIS–HCl containing 6 M urea (pH 8.2). This mode of apolipoprotein separation is based on differences in isoelectric points. Chromatography of VLDL and HDL apolipoproteins is performed on anion-exchange columns such as SynChropak AX300 (SynChrom IUC) and Mono Q-HR (Pharmacia).

A rapid and highly efficient technique for monitoring heterogeneity in apolipoproteins is the separation on the basis of differences in hydrophobicity by RPHPLC. Unfortunately, the small amounts of apolipoprotein (50–100 µg) which may be loaded, render this method qualitative but highly resolutive. Successful separations of apoA and apoC were performed on C-18 columns with a gradient of acetonitrile–water in the presence of 0.1% of TFA. Figure 10 shows the separation of human apolipoproteins A-IV, A-I and E on a TSK Phenyl-5PW column.

**Figure 10** RPHPLC separation of delipidated rat HDL (200 mg protein) on a TSK Phenyl-5PW column. Gradient between 20 mM H₃PO₄ in water (pH 2.3) and 20 mM H₃PO₄ in 60% acetonitrile. Flow rate, 1 mL min⁻¹ at 45°C. Fractions were analyzed by SDS/PAGE and their lipoprotein contents as assessed by Comassie Brilliant Blue staining (bold bars) and by silver staining (normal) are as indicated. ### 5 CURRENT TRENDS

#### 5.1 Membrane Proteins

##### 5.1.1 Perfusion Chromatography

The advent of perfusion chromatography, which consists of matrix containing flow-through particles, has further increased the interest in using HPLC systems, especially for membrane proteins. In contrast to conventional particles, the new matrix has two classes of pores. Large “throughpores” allow convective flow through the particles, quickly carrying sample molecules to short “diffusive” pores inside. By reducing the distance and therefore the time over which molecules diffuse to access the particle binding surface area, the flow rate can be increased 10–100-fold with little or no loss in resolution or capacity. Thus, once a particular mode of chromatography has been selected, it is possible to perform it by using perfusion particles. In general, the perfusion chromatography allows:

- routine achievement of high-resolution laboratory-scale separations in 30 s–3 min;
- rapid and systematic determination of the best separation method for optimum purity;
- a significant reduction in the time to process large-volume samples;
- improved yields and recoveries of biological activity through faster processing.
5.1.2 High-performance Liquid Chromatography Coupled On-line with Mass Spectrometry

Further developments in HPLC system have been achieved by coupling the outlet on-line with other instrumentation. The introduction of electrospray ion sources that are coupled with quadrupole mass filters has produced a mass spectrometer that is easily compatible with HPLC and CE, and therefore analysis and measurement of biological samples at a reasonable cost may be performed. Since most MS ion sources require lower flow rates than common chromatographic levels, a split of the HPLC eluent stream must be accomplished. Such systems are highly advantageous in that they facilitate the simultaneous separation of complex mixtures along with ultraviolet (UV) adsorption and mass detection.

With regard to the separation of thylakoid proteins of the PSII, RPHPLC interfaced with MS with an electrospray ion source allows the separation and accurate molecular mass determination of the individual membrane proteins contained in each peak on the HPLC trace, in particular for the identification of the major light-harvesting complex LHCII and minor (CP24, CP26, and CP29) antenna system, whose molecular masses range between 22 and 29 kDa.

Table 2 reports the comparison of the molecular mass values calculated from the protein sequence derived from the isolated genes with those determined by reversed-phase high-performance liquid chromatography/electrospray mass spectrometry (RPHPLC/ESIMS) together with the apparent molecular masses given by SDS/PAGE. The molecular mass values determined are in good agreement with the computed molecular masses of these proteins based on their DNA sequences. Thus, the assignment of each peak resolved by RPHPLC performed as above by electrophoresis, immunoblotting, and amino acid sequencing is corroborated by the values of molecular masses determined by the combined use of HPLC coupled on-line with a mass spectrometer equipped with an electrospray ion source (ESIMS). Furthermore, the resolution of two variants of type I proteins is in agreement with previous findings reporting the resolution of more than one type I protein by both high-resolution polyacrylamide gel electrophoresis and HPLC and is consistent with the high copy numbers of Lhcb1 genes isolated in higher plants, giving confidence in the real potential of these coupled techniques. On the other hand, the isolation of multiple copy numbers of the same gene from several higher plant species accounts for the resolution of different variants of the same proteins reported in the literature.

In the case of glycoproteins, ESIMS can detect whether an oligosaccharide is O or N-linked. It can also differentiate between complex, high-mannose, or hybrid forms. Moreover, this technique may be used to gain limited linkage order information using collision induced dissociation (CID) with both a single- and a triple-quadrupole mass spectrometer. In fact, in a complex map the region of the map that contains the glycopeptides can be deduced by looking for characteristic patterns in the two-dimensional (2D) plot or by the observation of oxonium ions produced by CID. The plot of m/z against retention time (contour maps) as a facile approach to the rapid 2D mapping of complex samples has some similarity to the popular 2D techniques currently used in biochemistry, such as a combination of IEF and SDS/PAGE, but offers a different combination of orthogonal separation methods. Such maps are readily available from the data generated by an HPLC/MS analysis and can give valuable information about glycosylation patterns and product consistency.

This new analytical method can be used to deduce possible carbohydrate structures by determining both the mass and elution position of individual glycopeptides.

RPHPLC/ESIMS has greatly expanded the power of peptide mapping to identify carbohydrate structures that are attached to asparagine, serine, or threonine.

residues. One can use in-source CID to scan the map for regions with a high concentration of glycopeptides. Such information should prove invaluable in determining the role in biology of the carbohydrate moiety in glycoproteins and in reducing the approval barriers for the pharmaceutical use of glycosylated proteins produced by mammalian fermentation systems.

5.1.3 High-performance Liquid Chromatography Coupled On-line with Light Scattering, Ultraviolet Absorbance and Refractive Index Detectors

Since protein molecules self-associate to oligomers for specific purposes and we often have no idea whether the protein exists in solution as a monomer, dimer, or other oligomer, the possibility of determining the molecular weights of proteins or their complexes is an important step in understanding proteins and their functions. In addition to HPLC coupled on-line with a mass spectrometer, techniques of using SEC with on-line light-scattering, UV absorbance, and refractive index detectors have recently been reported. Conventional SEC is a simple and fast method for estimating the molecular mass of a protein in its native form based on its elution position. However, there are several problems with this simple SEC approach. One is that the elution position depends not only on the molecular mass of the protein but also on its shape. Another problem is that the elution position will change if the protein has any tendency to interact with the column matrix. In addition, when a protein or a protein complex contains carbohydrates, the carbohydrates usually have a disproportionately large effect on its elution position, so SEC may not be able to determine its polypeptide molecular mass. However, as reported by Wen et al., by using two or more detectors proteins and glycoproteins may be easily determined.

5.1.4 Affinity Chromatography and Biosensors

Affinity chromatography, which in the past yielded success as a preparative tool, has stimulated the development of analytical applications for biomolecular recognition and most recently of molecular recognition biosensors. Affinity-based methods on other solid-phase surfaces such as blots and microliter plates have further expanded affinity-based technology. The principles of analytical affinity chromatography recently have been adapted for a nonchromatographic affinity technology, namely real-time optical biosensors for interaction analysis. As a real-time method, biosensors offer the opportunity to measure not only the equilibrium affinity constant but also the on and off rate constants for interactions of biological macromolecules.

5.2 Lipoproteins

CCC is a generic name for various liquid–liquid partition chromatographic methods which are used without solid support matrices. The stationary phase is retained in the column with the aid of gravity or centrifugal force. In this way the system eliminates all complications arising from the solid support. Previous studies have shown that a mixture of HDL and LDL fractions prepared by ultracentrifugation could be separated by x-axis ultracentrifugation. Recently the complementary use of CCC was attempted for the separation of three main classes of lipoproteins. Consequently, the fractionation of HDLs, VLDLs and LDLs may be performed by the combined use of polymer-phase CCC and hydroxyapatite chromatography without prior ultracentrifugation.

In the last decade, CE has emerged as a powerful separation technique for separation of plasma apolipoproteins. By adding the surfactant SDS to the separation buffer, the main apolipoproteins of HDL (apoA-I and apoA-II) and LDL (apo-B) may be separated in a single run in less than 12 min. The CE separation of VLDL apolipoproteins has also been studied. High-performance capillary isoelectrophoresis (ITP) of lipoproteins has been reported, which provided for rapid screening of lipoprotein abnormalities.

6 COMPARISON WITH OTHER METHODS

To summarize, it is not surprising that HPLC techniques, given the wide versatility, relative ease of use and high resolution, may be considered the most valuable tool for the characterization of virtually any hydrophobic protein. New supports offer a good compromise between mechanical stability and nonspecific binding, and an excellent recovery of the protein loaded. Moreover, these matrices also have excellent chemical stability within the working range of biological separations. In this context, the use of a reversed phase C-4 column, where the interaction of proteins with the matrix is very soft, has allowed a good separation and the complete recovery of proteins when applied to the separation of photosynthetic apparatus. In this particular case, where the protein molecular masses are similar and the amino acid sequence is sufficiently conserved, electrophoresis and immunoblotting appeared expensive and technically demanding. Moreover, for quantitative analysis, traditional approaches by SDS/PAGE are not only cumbersome but also rather ineffective for evaluating differences in the relative quantity of each component unless time-consuming antibody titration is used.
In Table 3 are summarized the advantages and disadvantages of separations performed by HPLC with other alternative separation systems such as SDS/PAGE, IEF, and CE. The number of reports dealing with the separation of membrane proteins by high-performance CE is still rather small. First results indicate that virtually all methods used for the separation of water-soluble proteins can also be applied to the separation of hydrophilic membrane proteins. Apart from the guidelines mentioned above, the know-how acquired in high-performance CE and in the preparative free-flow (ITP) of serum lipoproteins can be transferred to the separation of membrane proteins. Recently, we have demonstrated that CZE can be successfully applied for the complete resolution of the LHCII thylakoid membrane proteins by using the neutral detergent OD at a concentration lower than its critical micelle concentration in the electrolyte solution. This method was revealed to be rapid and sensitive for identifying and determining quantitatively the several components of PSII, but the RPHPLC method, in addition to being rapid, simple, and precise, has proven to be effective at detecting differences in the protein components of LHCII isolated from different plants that might not be evidenced by denaturing SDS/PAGE, as in the case of many species (data not shown). In addition, the possibility of separating all protein components of the PSII major and minor antenna system in samples not subjected to sucrose-gradient ultracentrifugation, as in the case of injection of BBY, is expected to be advantageous for evaluating the relative content of the different protein components of PSII and their variation related to physiological adaptation to environmental conditions. The injection of BBY directly allows one to obtain an exact evaluation of the quantitative relationships between chlorophyll a/b binding present in PSII, avoiding fractionated separation, Coomassie Brilliant Blue staining, quantification by densitometry, and correction of the results according to the specific binding of Coomassie Brilliant Blue to isolated proteins, as required by SDS/PAGE. The use of this method in screening photosynthetic mutants and plants adapted to different environmental conditions will be useful in the elucidation of the composition and supramolecular organization of LHCII and will possibly increase the understanding of the molecular mechanisms underlying the physiological adaptations.

As shown in the application examples in section 4, all HPLC methods developed for membrane protein separations offer the further advantage of analyzing the content of each HPLC peak by a multidimensional approach. A single peak observed in the RPHPLC separation of a protein is not an indication that the protein is highly pure, because it is common for related substances to co-elute with the parent protein. The main peak can be isolated and reinjected into an alternative separation system such as an SDS/PAGE, IEF, CE, or dissimilar HPLC system, taking appropriate measures to avoid decomposition of the protein after collection from the HPLC system. If the HPLC solvent system is not compatible with the second separation system, or if suitable stability of the isolated main peak is not attainable, then the nonfractionated protein product can be subjected to one of the alternative separation procedures. On-line spectroscopic monitoring using diode-array detection can be of value in establishing peak purity in favorable cases, but usually protein spectra are too similar to provide much discrimination.

The RPHPLC/ESIMS method holds several advantages over SDS/PAGE, the conventional technique for studying membrane proteins, including better protein separation, mass accuracy, speed and efficiency. Our study has shown that RPHPLC/ESIMS is an effective method for separating and characterizing the integral membrane proteins comprising the PSII major and minor antenna system, both as isolated complexes by sucrose-gradient ultracentrifugation and as the BBY grana membrane preparation directly. In accordance with molecular genetic data reported in the literature, showing
that higher plants have several Lhcb1 genes encoding different type I proteins for each species, two type I proteins of similar molecular mass have been resolved in spinach leaves. The experimental data are in good agreement with the molecular masses of the individual antenna proteins calculated on the basis of their nucleotide-derived amino acid sequences. In addition, the RPHPLC/ESIMS method allows the separation of protein constituents of the major and minor antenna system which are not resolved by conventional SDS/PAGE methods. Other advantages of RPHPLC/ESIMS over SDS/PAGE include the accuracy in determining the molecular mass and the higher speed and efficiency.

The use of chromatographic methods offers the possibility of combining more techniques, and therefore both SEC and RPHPLC methods will be employed to provide high-resolution, quantitative data, in addition to various spectroscopic, electrophoretic, and immunoochemical procedures for more specialized purposes. Conventional electrophoretic techniques often do not directly add to the information obtained, because HPLC frequently offers better resolution of related substances. However, a key advantage of conventional electrophoretic techniques is the ability to detect virtually any protein, thereby ensuring that any unanticipated protein impurities would be detected. In developing the HPLC methods to be used in the battery of tests, one must also consider the information obtained from the other techniques and seek to understand the relationship between these sets of information. The objective of such an assessment is to obtain the maximum amount of relevant information consistent with an efficient use of analytical resources.

Concerning lipoproteins separation, it was reported in section 5 that by using CE, high separation efficiencies and short analysis times for lipoproteins can be achieved. CE exhibits advantages over HPLC for lipoprotein analysis: CE separations are faster and do not require the use of expensive columns, and CE does not suffer from slow mass transfer rates which lead to band broadening in HPLC separations of apolipoproteins. The main advantage of CE over conventional electrophoresis is speed and instrumental format, which eliminates the need for labor-intensive steps such as gel preparation and staining.

ACKNOWLEDGMENTS

I am grateful to former and present members of the research group who have contributed to much of the work presented in this review, and to Dr Anna Maria Timperio and Dr Sara Rinalducci for valuable assistance in the preparation of the manuscript. This work was supported by CE Project CIPA CT93 0202 and COST Contract ERB IC15CT 980126.

Electron spin resonance (ESR) is a powerful analytical tool used in protein and peptide biochemistry. It is used in the determination of secondary, tertiary and quaternary protein structure and associated conformational changes. Protein dynamics and the relative orientation of protein components in ordered systems can also be measured. The majority of proteins do not contain unpaired electrons whose spin transitions give rise to an ESR signal, hence necessitating the use of extrinsic probes called spin labels.

Spin labels are nitroxide derivatives with a stable unpaired electron and a functional group for specific attachment to the protein (covalent or as a ligand). The most popular covalent sites are cysteine residues, which, if necessary, can be introduced into the protein structure using molecular biology techniques.

The physical basis for nearly all ESR applications is the anisotropy of the nitroxide signal and the sensitivity of the ESR spectra to various relaxation pathways. The interaction between an electron of a spin label and an external magnetic field depends on their relative orientations. The splitting and the center of ESR spectra of an oriented sample are used to determine the orientation of labeled domains. For samples with little disorder the orientational sensitivity is better than 1°. The width of the signal is proportional to the orientational disorder, which is used to measure conformational heterogeneity of proteins.

If the spin label reorientates itself on the ESR timescale (nanoseconds) then the spectral anisotropy is averaged. The extent of averaging defines the ESR line shape which is used to determine the rotational rate and anisotropy of motion. The dynamic range of ESR is very broad, rotational correlation times range from $10^{-12}$ to $10^{-7}$ s for conventional ESR and the sensitivity can be extended to slower motions ($10^{-3}$ s) with nonlinear saturation transfer electron spin resonance (STESR). Protein (spin label) mobility is used to follow conformational changes, steric restrictions on the spin label and the formation of large complexes.

Spin labels are also sensitive to the presence of other paramagnetic species. Collisions with water and lipid-soluble relaxing agents provide additional relaxation pathways measured by changes in relaxation times. The probability of these collisions reflects the accessibility of a spin label to the relaxant. The periodic patterns along the polypeptide chain of this accessibility are used to determine the secondary and tertiary structure of proteins. In the presence of another bound spin label or a paramagnetic metal complexed by histidine residues, spectra become broadened by dipolar or exchange interactions. Both mechanisms depend on the distance between the paramagnetic centers. Thus ESR can be used to determine intra- and intermolecular distances. The range of sensitivity is 5–25 Å and there are intensive efforts to increase the upper range to >50 Å. ESR as a spectroscopic ruler is used in protein structure determination and the investigation of macromolecular assembly processes and protein folding.

The foremost limitation of spin labeling ESR is the necessity to modify a protein with a spin probe. In some cases, the spin labels may perturb protein function and therefore cannot be used for spectroscopy. However, even an unsuccessful modification that results in functional
loss identifies functional regions of proteins and as such represents successful “mutational analysis” experiments.

1 INTRODUCTION

A spinning electron orbiting around a nucleus is a magnetic dipole. When placed in an external magnetic field, the dipole aligns parallel or antiparallel with the external field. These two orientations of the magnet represent two energy levels, with the difference in energy levels of the electron spin proportional to the strength of the magnetic field. The electron can be excited from one level (i.e., parallel dipole orientation) to another (antiparallel orientation) by an oscillating magnetic field. The energy of the oscillating field has to match the energy difference between the two levels. For a free electron in a magnetic field with a strength of a few hundred gauss, the frequency range of the exciting field is in the microwave region of the electromagnetic wave spectrum. The resonance between the orbiting electron and the microwave field forms the basis of ESR, also known as electron paramagnetic resonance or electron magnetic resonance.

ESR is commonly used to investigate protein and peptide structure, particularly studies of molecular orientation, protein dynamics and ligand binding. Observation of a resonance requires samples containing an unpaired electron, e.g., transition metals or organic radicals. Proteins and peptides are generally not paramagnetic and therefore require the use of extrinsic probes called spin labels. Spin labels are derivatives of nitroxides, small stable organic radicals, which are covalently attached to protein side chains or to metabolic substrates. In the last decade, the development of site-directed spin labeling (SDSL), which utilizes molecular biology to introduce new labeling sites, has established ESR as a protein structural determination technique. Patterns of side-chain mobility, accessibility to quenchers and the measurement of distances between spin labels have allowed the determination of the secondary, tertiary and quaternary structure of proteins.

This article is focused exclusively on spin labeling applications in protein and peptide biochemistry. The vast literature on metalloproteins, photosynthesis and reactive radicals in biology is not discussed here, and interested readers are directed to the many excellent reviews on these topics.1–6

2 HISTORICAL PERSPECTIVE

The first ESR experiments were performed by Zavoisky at the University of Kazan (Russia) during the Second World War.7 Inspired by the experiments of Gorter8 and Rabbi et al.9 on paramagnetic relaxation and atomic beams, Zavoisky demonstrated resonance between microwaves and the precession of Cu2+ ions in a magnetic field. Resonance was observed as an absorption of microwaves whenever the frequency of the oscillating microwave field was equal to the ion precession frequency.

In the decade following the Second World War, ESR was the domain of physical chemists and physicists, with the first biological applications appearing in the mid-1950s. This early work included structural studies of metalloproteins,10 measurement of free radicals in biological tissues,11 carbonized carbohydrates,12 and X-ray irradiated silk and hair.13 Assenheim provides an excellent review of this early work with intrinsic ESR signals.14

In 1965, McConnell introduced extrinsic spin labels designed to label proteins. Using nitroxide derivatives first synthesized in Russia,15,16 McConnell et al. demonstrated a helix–coil transition of a polylysine peptide.17 Since then, ESR spin labeling has been used to study conformational changes in a number of proteins modified by maleimide nitroxides, which specifically target cysteine residues. However, reliance on the naturally occurring cysteine residue was a severe limitation. The SDSL strategy developed by Hubbell in 1989 employs molecular biology to introduce new cysteines for spin label attachment. The use of SDSL to scan the protein sequence with cysteines has stimulated the resurgence of ESR as a structural biology method.

The methodology of ESR was also undergoing an evolution. In 1957, Feher invented electron–nuclear double resonance (ENDOR) spectroscopy, a combination of both ESR and nuclear magnetic resonance (NMR),18 in which nuclear spin transitions are observed indirectly by monitoring electron spin transitions. A few years later, electron–electron double resonance (ELDOR) spectroscopy was developed by Hyde et al.19 and Benderskii et al.20 which allowed the measurement of spectral diffusion between distinct spin populations. The development of spin-echo instruments by Mims et al.21 introduced time-domain ESR in the 1960s. This was followed by Fourier transform electron spin resonance (FTESR), developed independently in the 1980s by Elia and Freed.22 Dinse et al.23 and Bowman.24 The first spin label applications appeared in 1986 when Gorester and Freed performed two-dimensional (2-D) FTESR experiments to measure spin dynamics.25

ESR moved towards high field (high frequency) with Lebedev et al.’s construction of a 150-GHz spectrometer,26 followed by Freed et al.’s 250-GHz spectrometer, which was based on quasi-optics. The latter instrument was used extensively to investigate spin labels
3 SAMPLE PREPARATION

3.1 Nitroxide Spin Labels

Proteins are ESR silent, with the exception of metalloproteins, and must therefore be “labeled” with paramagnetic probes. These probes, or spin labels, are nitroxide derivatives containing an unpaired electron in the \( p^* \) orbital of the N–O bond (Figure 1a–c). The nitroxide radical is stable owing to the presence of methyl groups on neighboring carbon atoms. To limit flexibility, the NO group is enclosed in either a six-membered piperidine or a five-membered pyrrole ring. Pyrrole rings with an unsaturated bond are the least flexible.

The unpaired electron in the \( p^* \) orbital also interacts with the spin of the nitrogen nucleus, splitting the ESR signal into resonances corresponding to different nitrogen nuclear manifolds. Thus, the number of resonant peaks depends on the nitrogen isotope, three for \( ^{14}\text{N} \) and two for \( ^{15}\text{N} \). \( ^{15}\text{N} \) labels have the advantage of less spectral dispersion which increases the signal amplitude 1.5-fold in conventional ESR and allows for full spectral coverage in FTESR. Reduction of the nuclear manifolds also simplifies the interpretation of nuclear relaxation and accelerates computer simulations of ESR line shapes. \( ^{15}\text{N} \) labels, however, are considerably more expensive than \( ^{14}\text{N} \) and only a handful of them are available commercially.

A weaker interaction occurs between the electron spin and the hydrogen nuclei of the ring and methyl groups. Each resonance peak is split by the nuclear spin, but the splittings are unresolved, resulting in a broad peak. The broadening can be removed by the substitution of hydrogen with deuterium which increases the peak height 1.5-fold for Gaussian and 5-fold for Lorentzian lines.

![Figure 1](image1.png)

**Figure 1** Commonly used nitroxides: (a) six-membered piperidine ring; (b) saturated five-membered pyrrole ring; (c) unsaturated pyrrolidine ring.

3.2 Labeled Sites

Nitroxide spin labels are used either covalently as modifiers of selected amino acids or noncovalently as analogs of substrates or enzymatic cofactors. The specificity of the label is conferred by the functional group attached to the nitroxide. For example, maleimide, iodoacetamide, indanedione and \( \alpha \)-ketone groups attached to the nitroxide moiety target cysteine residues, while lysines are modified by activated esters in Figure 2(a–d). Attachment of the nitroxides by disulfide bonds allows for reversible modification. Reduction of the disulfide bonds with a mild reducing agent yields the unmodified protein. Bifunctional spin labels with two linker groups facilitate attachment to two sites on a protein, reducing probe mobility with respect to the protein. The ability to engineer neighboring attachment sites in a protein using molecular biology is likely to increase the use of bifunctional labels.
